Since the original publication of this report, an error was discovered in the calculation procedure for primary productivity. Table 7 is reproduced in this revised report with the corrected values. The average gross primary productivity for 1973 was 1156 mg C/m³/day rather than 1864 mg C/m³/day as reported originally.

SUMMARY

The results of the initial 18 months of the chemical and biological studies of Lake Okeechobee have provided some reliable baseline data on the Lake. The inferences made from this study are based on one year's data and may be amended when more data becomes available.

Comparison of average nitrogen and phosphorus levels in the Lake with previously reported levels does not show any significant increases during the last five years. There were, however, significant areal and seasonal variations in these nutrient parameters during this study. Generally, nutrient values were higher during the dry winter months and lower during the wet summer months. The areal distribution was related to both major inflows and bottom sediment characteristics. Based on yearly average values, phosphate levels were highest in the northern section of the Lake while the highest nitrogen concentrations appeared in the southern section.

The average gross primary productivity for Lake Okeechobee in 1973 was 1865 mg C/m³/day; the average net primary productivity (1794 mg C/m³/day) was essentially the same.

Peaks in primary productivity occurred in the spring (March and April), early summer (June), and fall (August - October). The highest productivities of the study period were observed in the fall. The magnitude and timing of the peaks varied from location to location. The data for the spring peak was incomplete but did indicate lower productivities than in the fall. The productivities for the early summer peak were lower still. The north and north-central areas of the Lake were the most productive; the southern and western portions were less so.

Small, flagellated, unicellular, green algae appeared to be responsible for much of the primary productivity occurring in the Lake.

Blue-green algae (Cyanophyta) dominated the phytoplankton of Lake Okeechobee. Also present, in order of decreasing abundance, were green algae (Chlorophyta), diatoms (Chrysophyta), and euglenoids (Euglenophyta).

Two pronounced maxima in phytoplankton densities were observed, one in the spring and one in the fall. The spring pulse (March - May) was composed initially of small, flagellated, unicellular green algae. They were succeeded by larger populations of filamentous blue-green algae and diatoms. The fall pulse had lower phytoplankton densities and was of longer duration than the spring pulse. The peak in phytoplankton densities during the fall was observed in September. This pulse was composed initially of filamentous blue-green algae, which were succeeded by large populations of colonial blue-green algae and small, flagellated, unicellular green algae.

Resident algal populations were shown to differ within the Lake. Peripheral areas near Fisheating Creek and the Kissimmee River-Nubbin Slough complex averaged more blue-green algae than did other areas in the Lake. Green algae were more abundant at the southern end of the Lake. The central areas of the Lake exhibited more temporal shifts in algal populations than did peripheral areas.

In terms of nutrient loadings, some of the less significant water inflows were highly significant sources of nitrogen and phosphorus. Nubbin Slough, which discharged less than 7% of the total inflow into the Lake from May 1973 to May 1974, accounted for 40% of the total phosphate loading. Similarly, the agricultural canals (Miami, North New River and Hillsboro Canals) contributed only 9% of the total water inflow but 32% of the total nitrogen loading.

The Kissimmee River and direct rainfall into the Lake were each responsible for approximately 35% of the total water input. However, chemistry data indicates

that these two major sources of water are not the major sources of nutrients. Rainfall supplied only limited amounts of nutrients due to the low concentration of nutrients in rain. Although the Kissimmee River supplied significant quantities of nitrogen (30%) and phosphorus (21%) to Lake Okeechobee, the high loadings were primarily due to high discharge rather than high concentrations of nutrients. In fact, the average concentrations in the River were very similar to the average Lake concentrations.

The high phosphate loadings for Nubbin Slough and the high nitrogen loadings from agricultural canals to the south of the Lake may indicate a general relationship between land use and run-off water quality. The possible concentration of animal waste in the nubbin Slough drainage basin may be responsible for the high phosphate values while nitrification and subsequent leaching in the Everglades agricultural area could account for high nitrate nitrogen concentrations in the run-off water.

Chemistry data from Lake sampling stations near the major discharge points do not immediately reflect the high nutrient loadings during July, August and September, although yearly averages of nutrient concentrations at peripheral stations do show the influence of the loadings. Rapid biological uptake of incoming nutrients may account for the delay in impact on chemistry data. The nutrient budgets, the high primary productivity rates, and the response of phytoplankton populations to loadings suggest biological uptake of nutrient loadings.

The timing and magnitude of the fall phytoplankton and primary productivity peaks at the peripheral stations appeared to be related to the nutrient loadings of the proximal inflows. The data indicates probable relationships between orthophosphate loadings and blue-green algae in the northern end of the Lake and between nitrate loadings and green algae in the southern end.

Although biological processes may be responsible for the rapid assimilation of nutrient loadings during the periods of high discharges and subsequently for the low summer value of ambient materials, the results of regression analyses indicate that nutrient variations within the Lake are primarily dependent upon physical processes. Variations in both dissolved and total species of nitrogen and phosphorus were found to be related to wind stress and sediment characteristics at each station. Generally increased nutrient values were associated with increased wind stress (wave action) which occurred primarily during the winter months. There was also a tendency for nutrient values to be higher at stations where the sediments were predominantly mud or silt.

Regression analysis showed only occasional significant relationships between biological activity (primary productivity and phytoplankton densities) and chemical or physical processes.

The application of the chemical and biological data to several different methods of establishing trophic levels of lakes indicate that Lake Okeechobee would be classically defined as an early eutrophic lake. However, sufficient data are not available to determine whether or not this condition is a result of recent cultural eutrophication or the "natural" condition of the Lake.

Establishing the trophic state of Lake Okeechobee may be somewhat misleading since the concept of trophic state indicators and trophic levels have classically been applied to temperate region lakes and Lake Okeechobee lies within the semi-tropical climatic zone.

INTRODUCTION

Lake Okeechobee lies in the center of Florida approximately 200 miles north of the southern tip of the peninsula. As the major storage basin for surface water in southern Florida, the Lake is a highly significant part of the Central and Southern Florida Flood Control Project which was authorized by the 80th Congress in 1948 (Figure 1). The Lake and its tributaries and distributaries have been considerably altered by various attempts at water management in the northern Everglades. Presently all major inflows and outflows associated with the Lake except for Fisheating Creek have some type of flow control structure. At several points, notably the Lake termini of the Miami, North New River and Hillsboro Canals, water can be made to flow into or out of the Lake depending upon flood control and water supply criteria. The Lake itself is surrounded by the Hoover Dike which has been constructed at approximately the 15 foot m.s.l. contour. The 25 foot high dike was designed to prevent damaging storm surges, which may accompany tropical storms, from flooding developed land adjacent to the Lake.

The original condition of the Lake can only be inferred from journals and other writings of early visitors to the Lake. Brooks (1974) gives a summary of many of these reports which indicate that the original Lake had a variable but considerably greater depth than the present mean depth of 3 meters and a much less defined shoreline.

There have been only limited previous studies of the chemical and biological characteristics of Lake Okeechobee. In 1940 the United States Geological Survey (USGS) sampled Lake Okeechobee as part of their survey of surface water quality in the Southeast region of the United States (Parker,et al., 1955). The results of chemical analysis on these samples indicated that the Lake contained signifi-

THE STATE OF FLORIDA
AND THE
CENTRAL AND SOUTHERN FLORIDA
FLOOD CONTROL DISTRICT

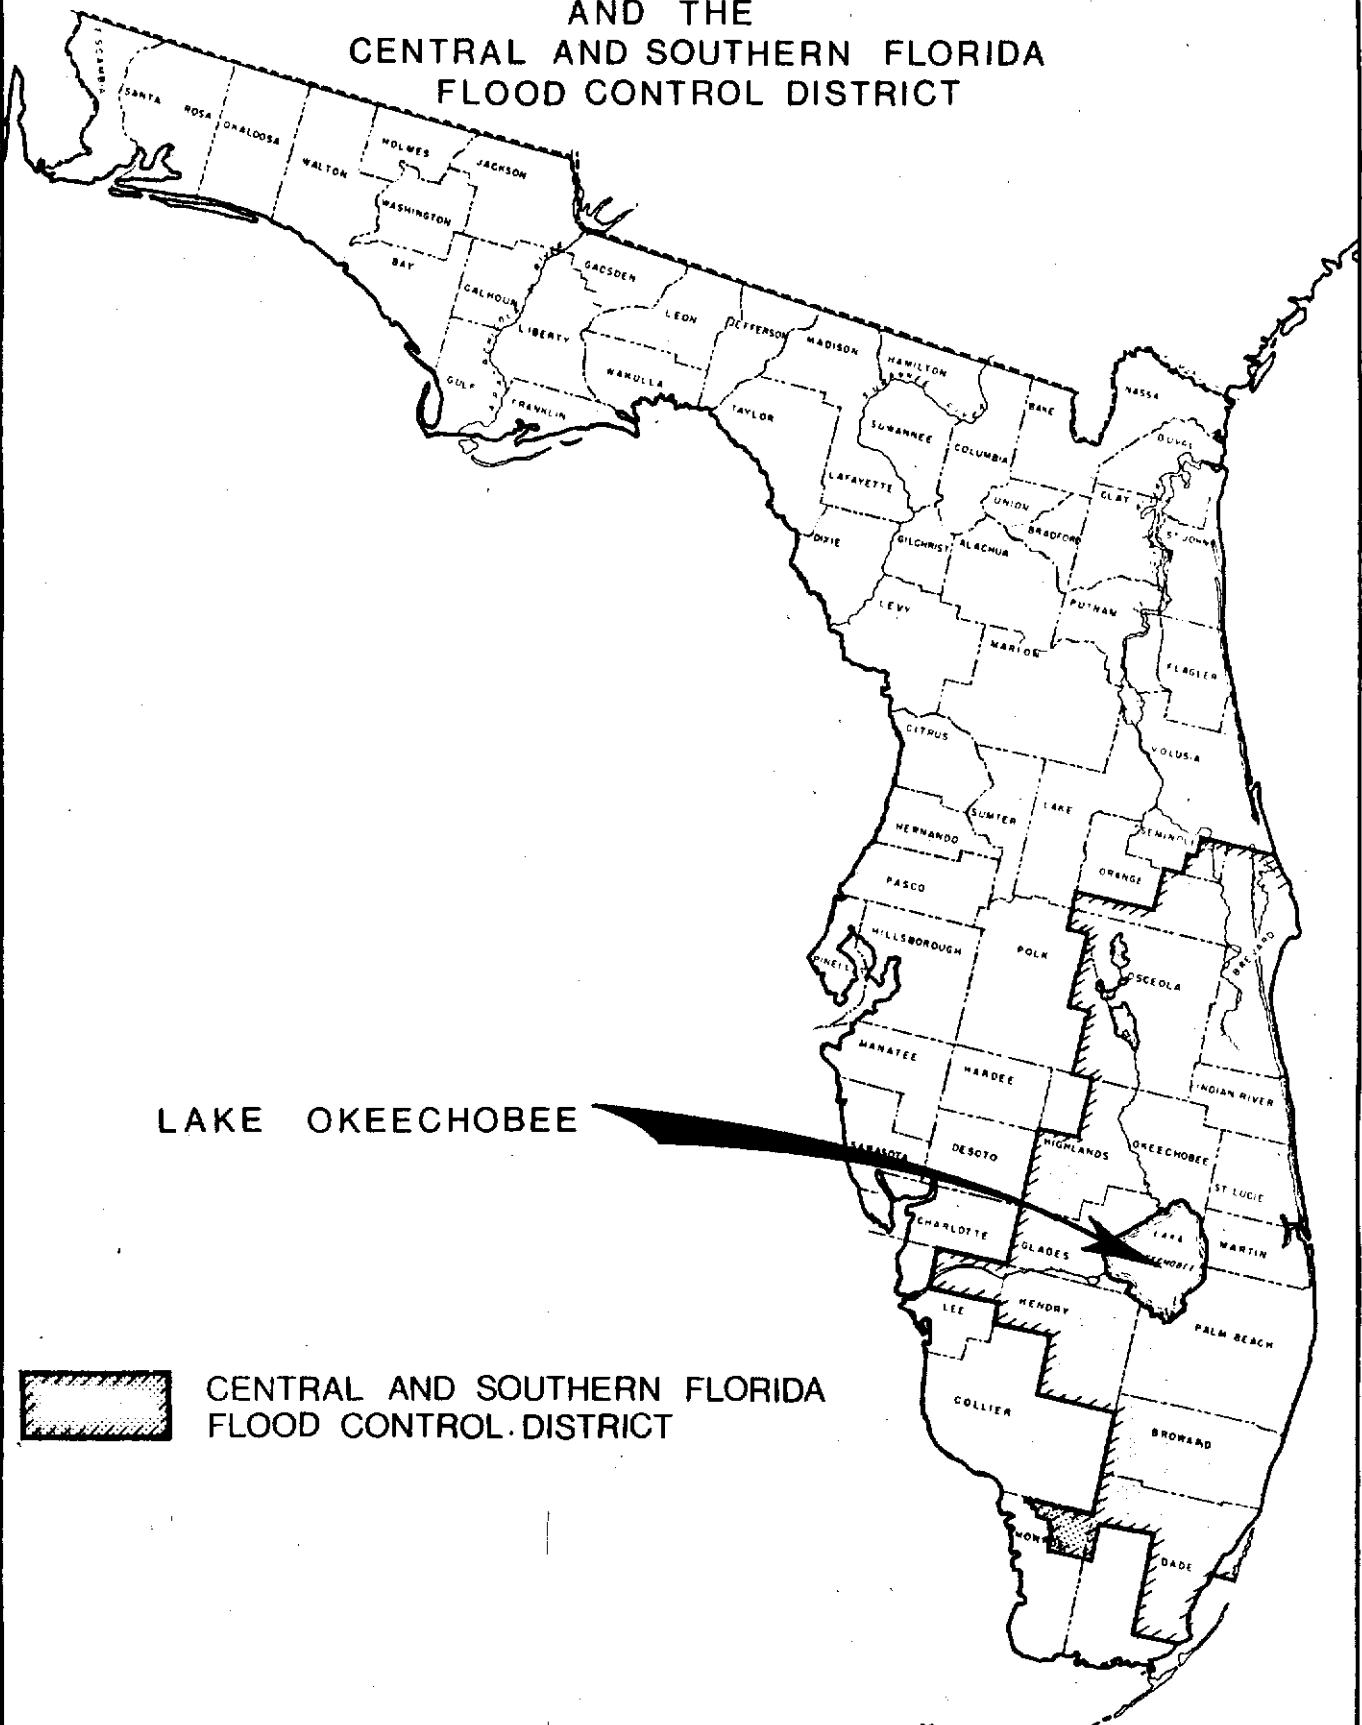

FIGURE 1

cantly higher concentrations of major ions than could apparently be accounted for by the inflows to the Lake. The high dissolved solids of the lake water were attributed to dissolution of calcareous sediments in the Lake. During the years 1969 to 1972 the USGS undertook a much more intensive study of the Lake in cooperation with the Central and Southern Florida Flood Control District (FCD). The results of this study (Joyner, 1972) indicated that the Lake was receiving and storing considerable amounts of nutrients. Mass balance calculations for total dissolved solids indicated, as did the 1940 report, that unaccounted for sources of major ions must exist. This USGS report concluded that chemical and biological characteristics of the Lake were indicative of an early eutrophic condition.

Since Lake Okeechobee represents an important natural resource in terms of a wildlife habitat and major freshwater reservoir, the FCD decided to initiate its own environmental investigations of the Lake. This decision was made based on the realization that the Lake and its tributaries were being exposed to ever increasing environmental stresses and that the recent USGS report indicated that early eutrophic conditions already existed within the Lake. In order to fully evaluate current and future stresses on the Lake, a broad range of studies were developed. This report is limited to only a part of these studies. It concerns the results of chemical and biological investigations of the Lake's limnetic zone from January 1973 to July 1974.

Goals

The overall goal of this and other studies of Lake Okeechobee is to increase the knowledge of the various natural systems related to the Lake and the interactions between these systems. This information will be necessary to make a proper management decision if the Lake is to be maintained as a natural resource.

The specific objectives of the chemical and biological studies of Lake Okeechobee may be summarized as follows:

1. Provide continuity in base line water chemistry data by interfacing with the previous USGS study.
2. Calculations of loading rates and materials budgets of the Lake for both nutrients and major ions.
3. Determine systematic relationships among biological, chemical, and physical factors.
4. Assessment of the Lake's current trophic state using primary productivity, algal populations, benthic invertebrates and ambient water quality data.
5. Provide base line and/or input data to other studies concurrently being conducted within Lake Okeechobee.

Morphology

Lake Okeechobee is thought to be approximately 4,000 - 6,000 years old (Brooks, 1974). It is considered to have been formed as the result of the subsidence of Miocene clays. As the subsequent depression filled with fresh-water the natural outlets became blocked by vegetation. The Lake reached its modern size and shape in approximately 265 A.D., when all natural outlets of the Lake became filled by organic sills. From that time until the present drainage attempts, the only major loss of water from the Lake other than evaporation was a sheet flow to the south.

Lake Okeechobee, which is at approximately 27° N Latitude and 80° W Longitude, is one of only a few fresh water lakes occurring within the semitropics. Most other lakes within the latitudinal range of 30° N and 30° S latitude are either deep mountain lakes or temporary saline lakes.

The surface area of Lake Okeechobee, 1820 km^2 (450,000 acres) makes it one of the largest lakes in the United States. However, the mean depth of the Lake is usually less than 3 meters with the maximum depth of less than 5 meters. The lake surface is somewhat pie-shaped with the apex of the wedge on the western shore. The longest axis, is about 55 km (35 miles) and runs north to south. The east-west axis is about 49 km (30 miles). There are extensive littoral zones on the south, west, and northwest shores of the Lake. The Lake basin is saucer-shaped with the lowest contour just below mean sea level.

Hydroperiod

The level of water in Lake Okeechobee is currently regulated between 14.0' m.s.l. and 16.0' m.s.l. for flood control and water supply needs. The lower lake stages are maintained during the summer and early fall to provide maximum flood control benefits while the high stages are designed to meet water supply needs during the dry winter and spring months.

In reality it is very difficult to maintain the regulation stages and Lake levels may ordinarily vary from 10.5' to 16.5' m.s.l. The difficulty in maintaining lake stages stems from variable climatic conditions and short water residence times. The highly variable rainfall rates in South Florida, especially during the wet months from June through October, provide substantially different quantities of water to Lake Okeechobee from year to year. Since the residence time of water in the Lake is approximately one year, the volume and stage of the Lake vary considerably.

The study period from January 1973 to June 1974 was one in which the rainfall rates and Lake hydroperiod were close to the normal or average events for the past 40 years.

Figure 2 shows the monthly rainfall rates in the Okeechobee area during

RAINFALL ON LAKE OKEECHOBEE
DEC. 1972 TO JUNE 1974

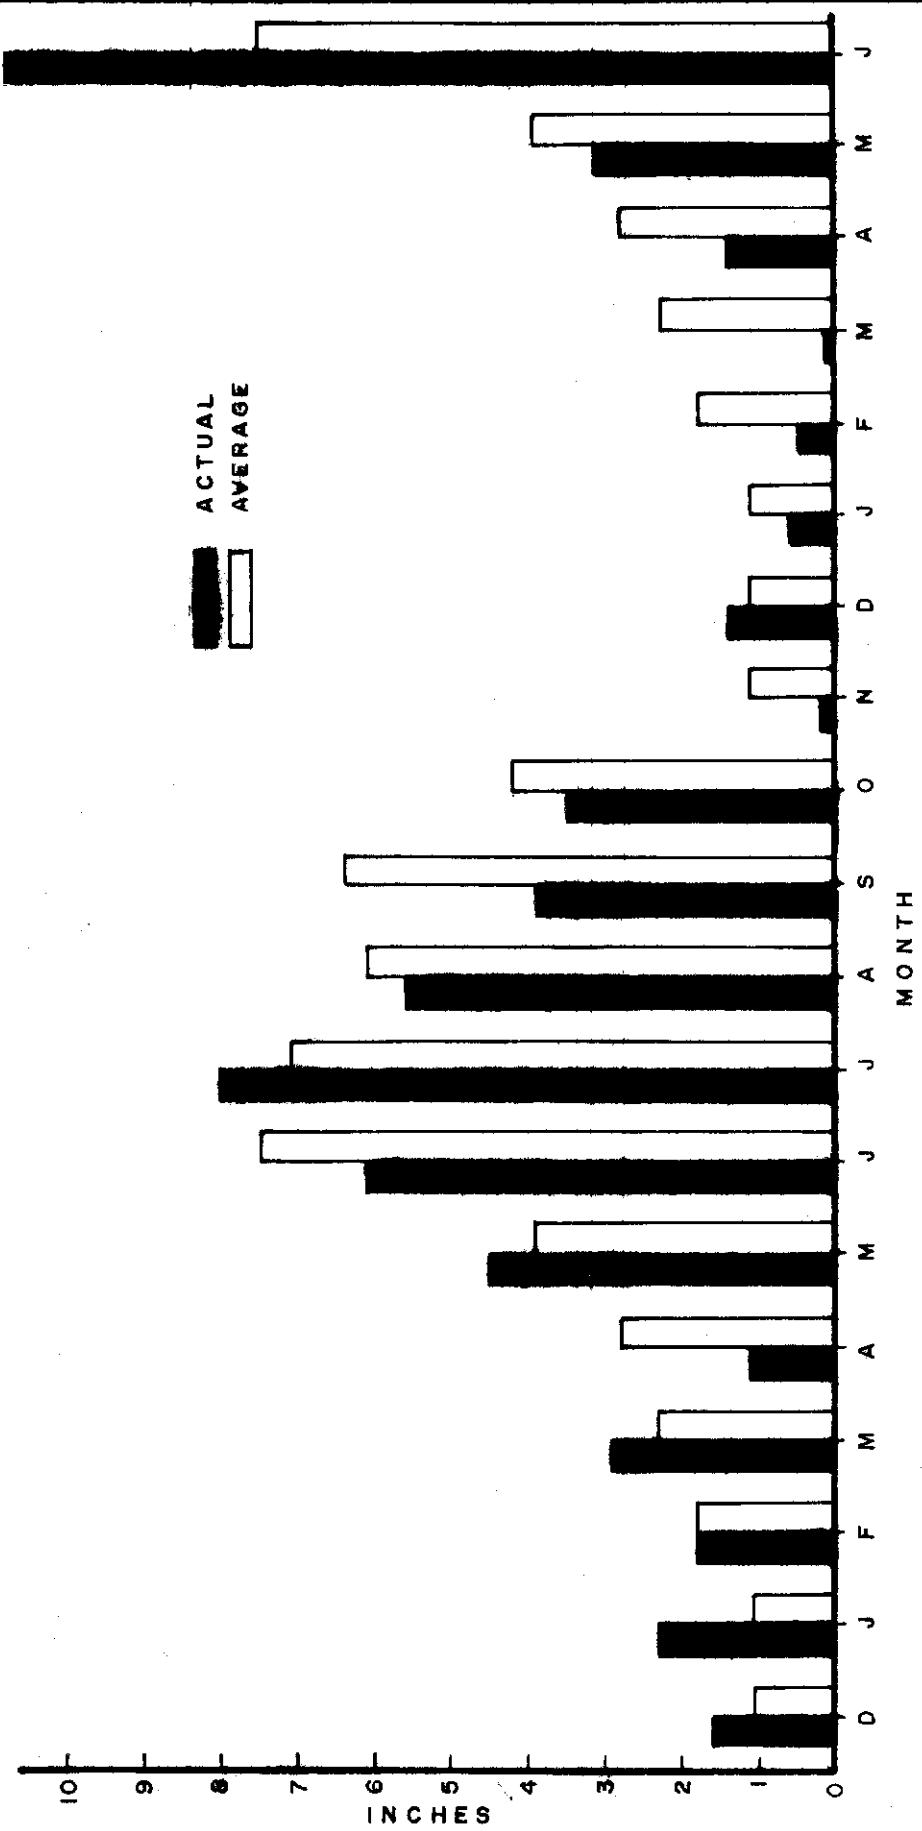

FIGURE 2

the period of the study. Figure 2 also shows the average rainfall for the area based on the 1930 to 1970 period of record. A total of 59 inches of rain fell during the initial 18 months of this study, which is only 6 inches less than the 65 inches which could normally be expected.

The mean monthly lake stages and average lake stage for the 1930 to 1970 period of record are shown in Figure 3. The stages were well below average during the first nine months of the study but rose to above average stage during the fall of 1973. The stage fell to below normal again during the first half of 1974. However, the above average rains in June 1974 continued throughout the summer causing lake stages to rise dramatically during this period to above average levels.

Drainage Basins

The major natural and man-made drainage basins to Lake Okeechobee are shown in Figure 4. The natural basins consist primarily of the Kissimmee River, Fisheating Creek and Taylor Creek. Nubbin Slough now includes most of Taylor Creek drainage basin due to flood control and water supply projects. The man-made drainage to the Lake includes the St. Lucie Canal, Hillsboro Canal, North New River Canal and the Miami Canal. These canals can convey water both into or out of the Lake depending upon flood control and water supply criteria. As mentioned earlier all inflows into the Lake except Fisheating Creek have flow control structures associated with them to maintain canal and groundwater levels in upland areas.

The total drainage basin of Lake Okeechobee including Lake Istokpoga drainage is approximately 4292 square miles. One half of this area is contained within the 2335 square mile Kissimmee River drainage basin. The next largest subdrainage basin is the 652 square mile Lake Istokpoga basin which can drain either into the

MEAN MONTHLY STAGE LAKE OKEECHOBEE
DEC. 1972 TO JUNE 1974

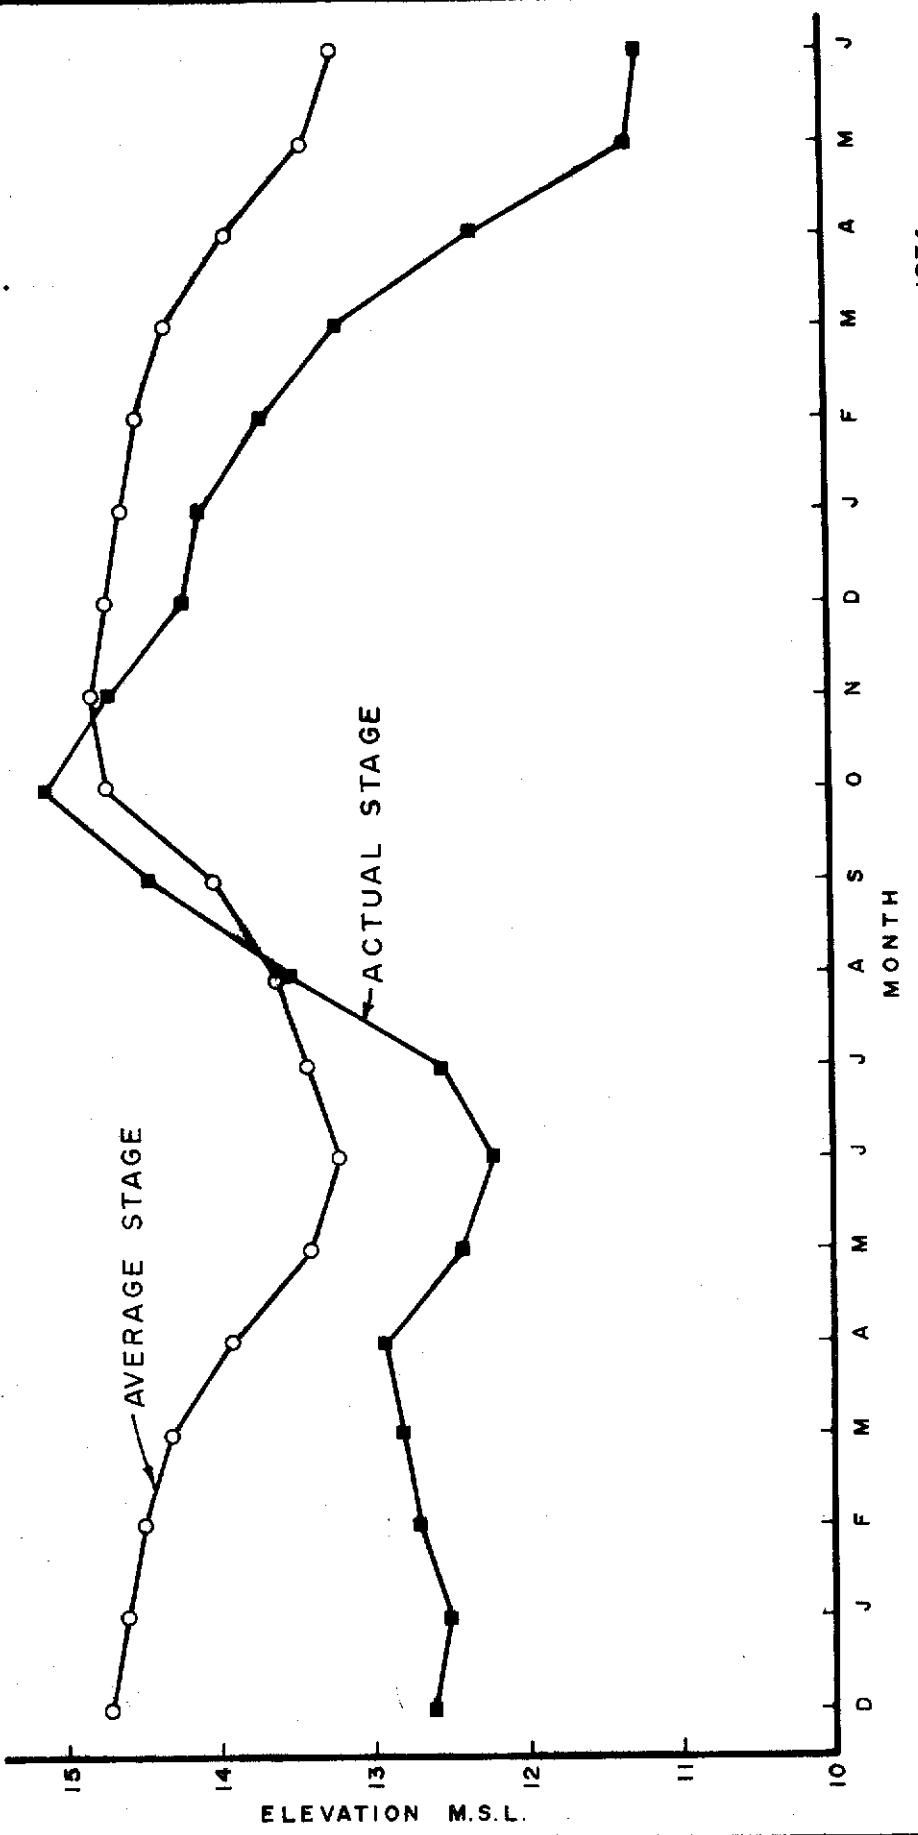

FIGURE 3

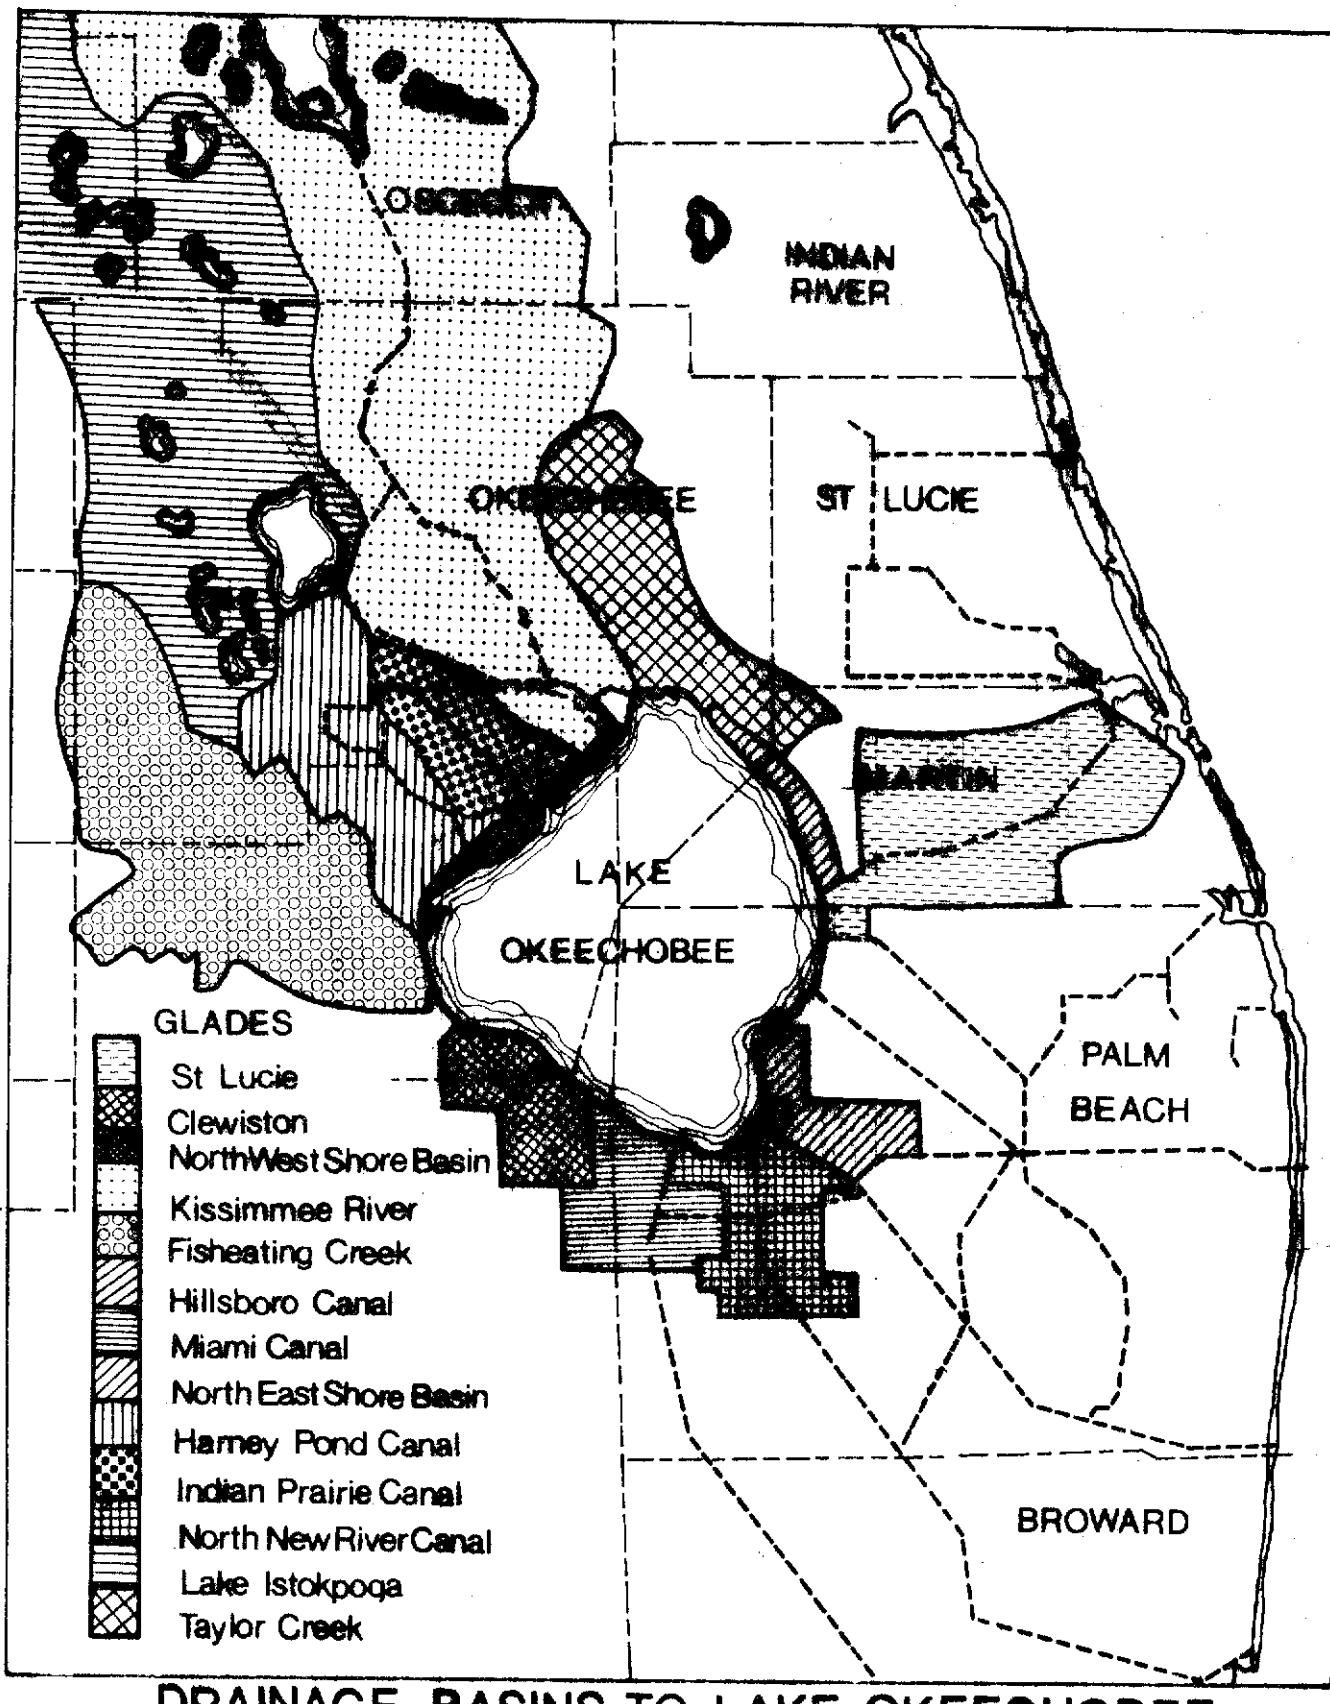

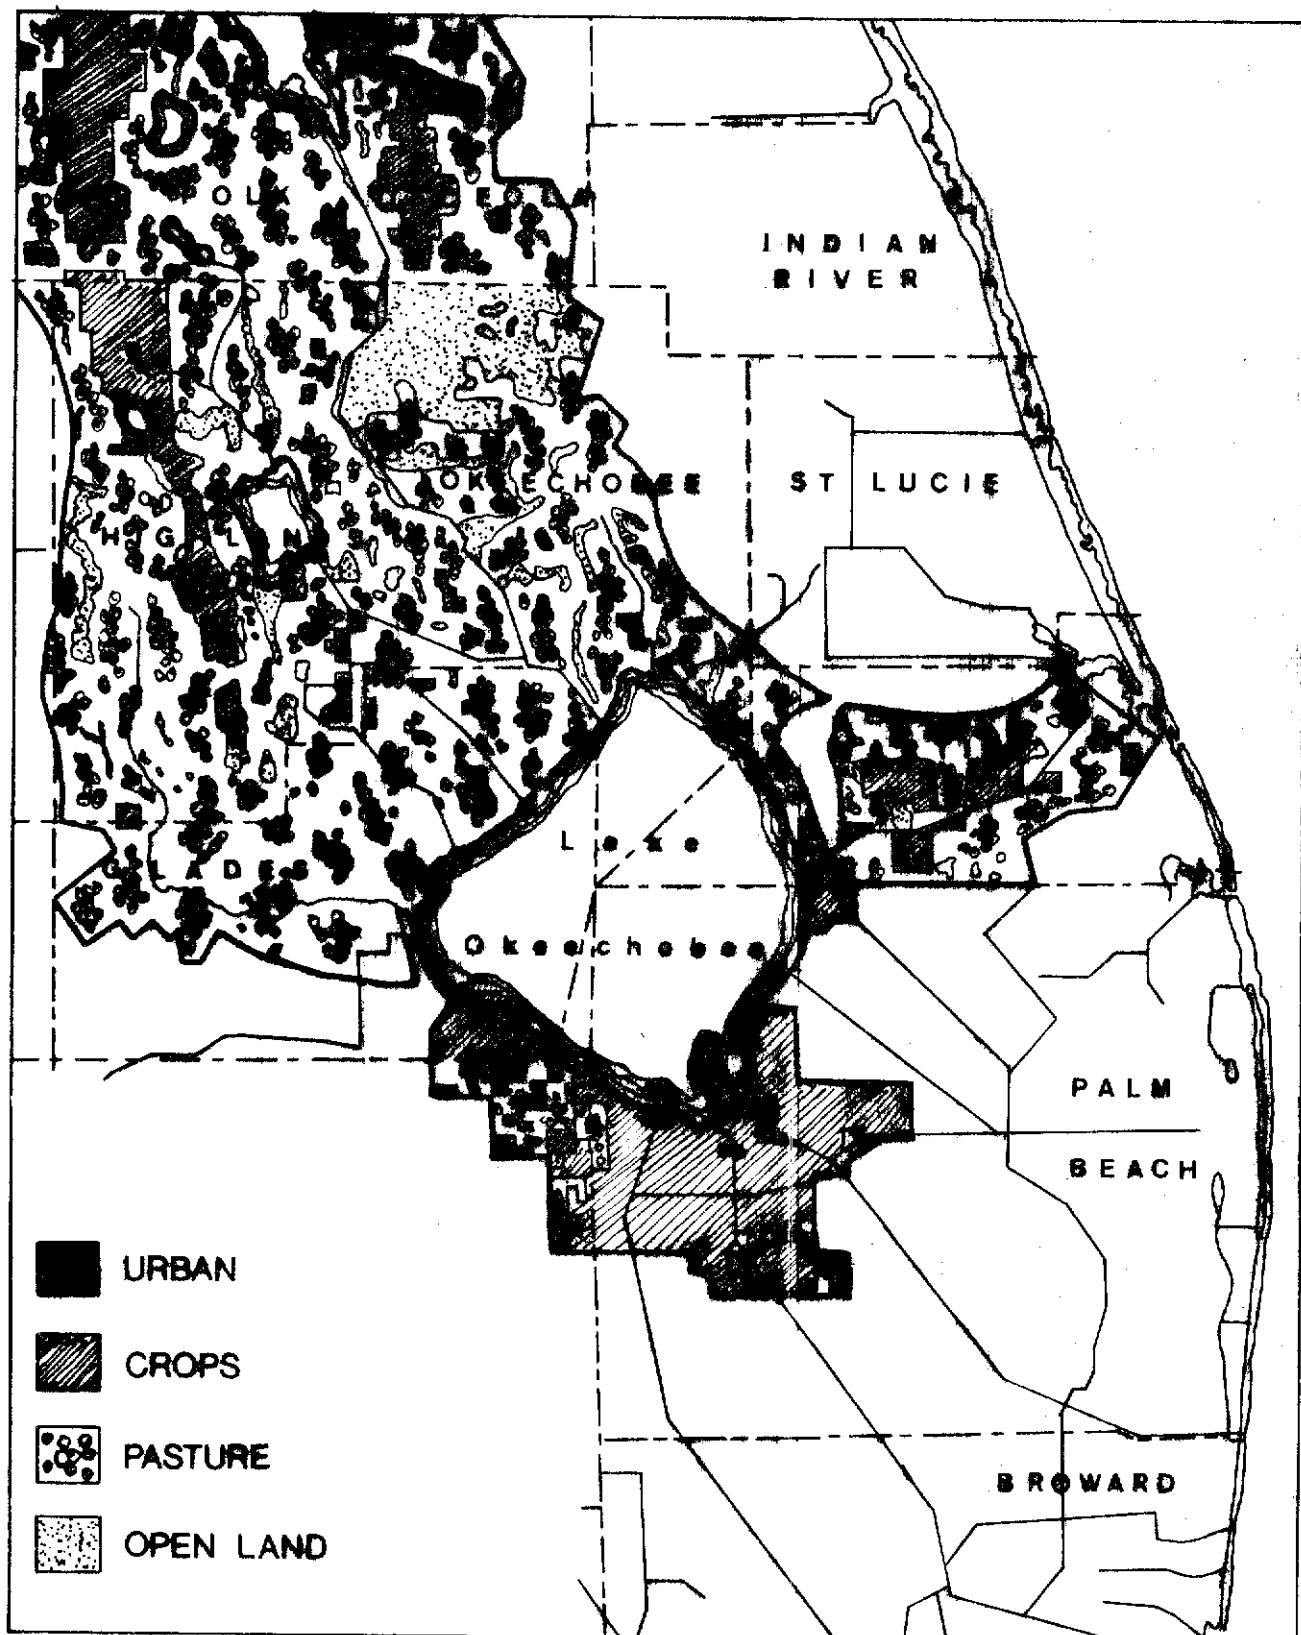

FIGURE 4

Kissimmee River or directly into Lake Okeechobee via the Harney Pond Canal or Indian Prairie Canal. Besides conveying water from Lake Istokpoga to Lake Okeechobee these two canals have additional drainage areas of 286 square miles. Fisheating Creek with a drainage area of 461 square miles has the third largest drainage area of all inflows to the Lake. The three agricultural canals - Miami, North New River and Hillsboro - have a combined drainage area of 311 square miles. Water which has drained into the north ends of these canals can be pumped into the Lake by FCD pump stations S-2 and S-3. Most of Taylor Creek and Nubbin Slough runoff now discharges into the Lake at a common point and the combined drainage area of this system is 184 square miles. It has been designated Taylor Creek Basin on Figure 4. The St. Lucie Canal periodically delivers water to Lake Okeechobee although in very minor amounts. It drains an area of approximately 250 square miles. The two areas on the map designated as the Northeast Shore and Northwest Shore Basins lie between the Lake levee and tieback levees for major inflows and are drained by several FCD pump stations.

The general land use patterns for the drainage basins to Lake Okeechobee are shown in Figure 5. The major land uses are either as pasture land or crop land. Pasture land use predominates in the Kissimmee River, Nubbin Slough, Indian Prairie Canal and Harney Pond Canal basins. The Nubbin Slough basin has particularly heavy dairy activity. The area to the south and east of the Lake which is drained by the Miami, North New River, Hillsboro and St. Lucie Canals is heavily devoted to both sugar cane and vegetable crops. There are only minor urban areas within any of the basins.

LAND USE MAP

FIGURE 5

MATERIALS AND METHODS

Sampling Locations and Frequencies

Figure 6 shows the location of all stations at which chemical and biological data were collected. The eight stations chosen for routine sampling were located to provide both representative lake data and to monitor the influence of major inputs into the Lake. Stations 1, 2 and 3 were located in the northern end of the Lake to provide data on the possible impact of discharges from the Kissimmee River and Nubbin Slough. Stations 6 and 7 were located in the south end of the Lake, to monitor the effects of backpumping from the North New River Canal (S-2) and the Miami Canal (S-3). Station 5 was located at the western edge of the Lake to measure the influence of Fisheating Creek and/or the extensive littoral area on the western and southwestern shores of the Lake. Stations 4 and 8 were designed to monitor the mid-lake conditions and were located as far from any major input as possible.

The semi-annual stations (10 through 16) provided data to evaluate areas of the Lake which were not routinely monitored and therefore test the effectiveness of the monitoring system.

Chemistry samples were collected monthly at Stations 1 through 8 from January 1973 through January 1974. Beginning in February 1974 chemistry samples were collected every two weeks at these stations. During the months of May and November, chemistry samples were collected at Stations 10 through 16 as well as 1 through 8.

Since January 1973, phytoplankton samples were collected at Stations 1 through 8 at monthly intervals to coincide with the chemistry sampling. Benthic invertebrate samples were also taken at these stations at quarterly intervals.

Primary productivity measurements were taken at monthly intervals at Stations 5 and 6 beginning in January 1973, and at Stations 1 and 4 beginning in March 1973.

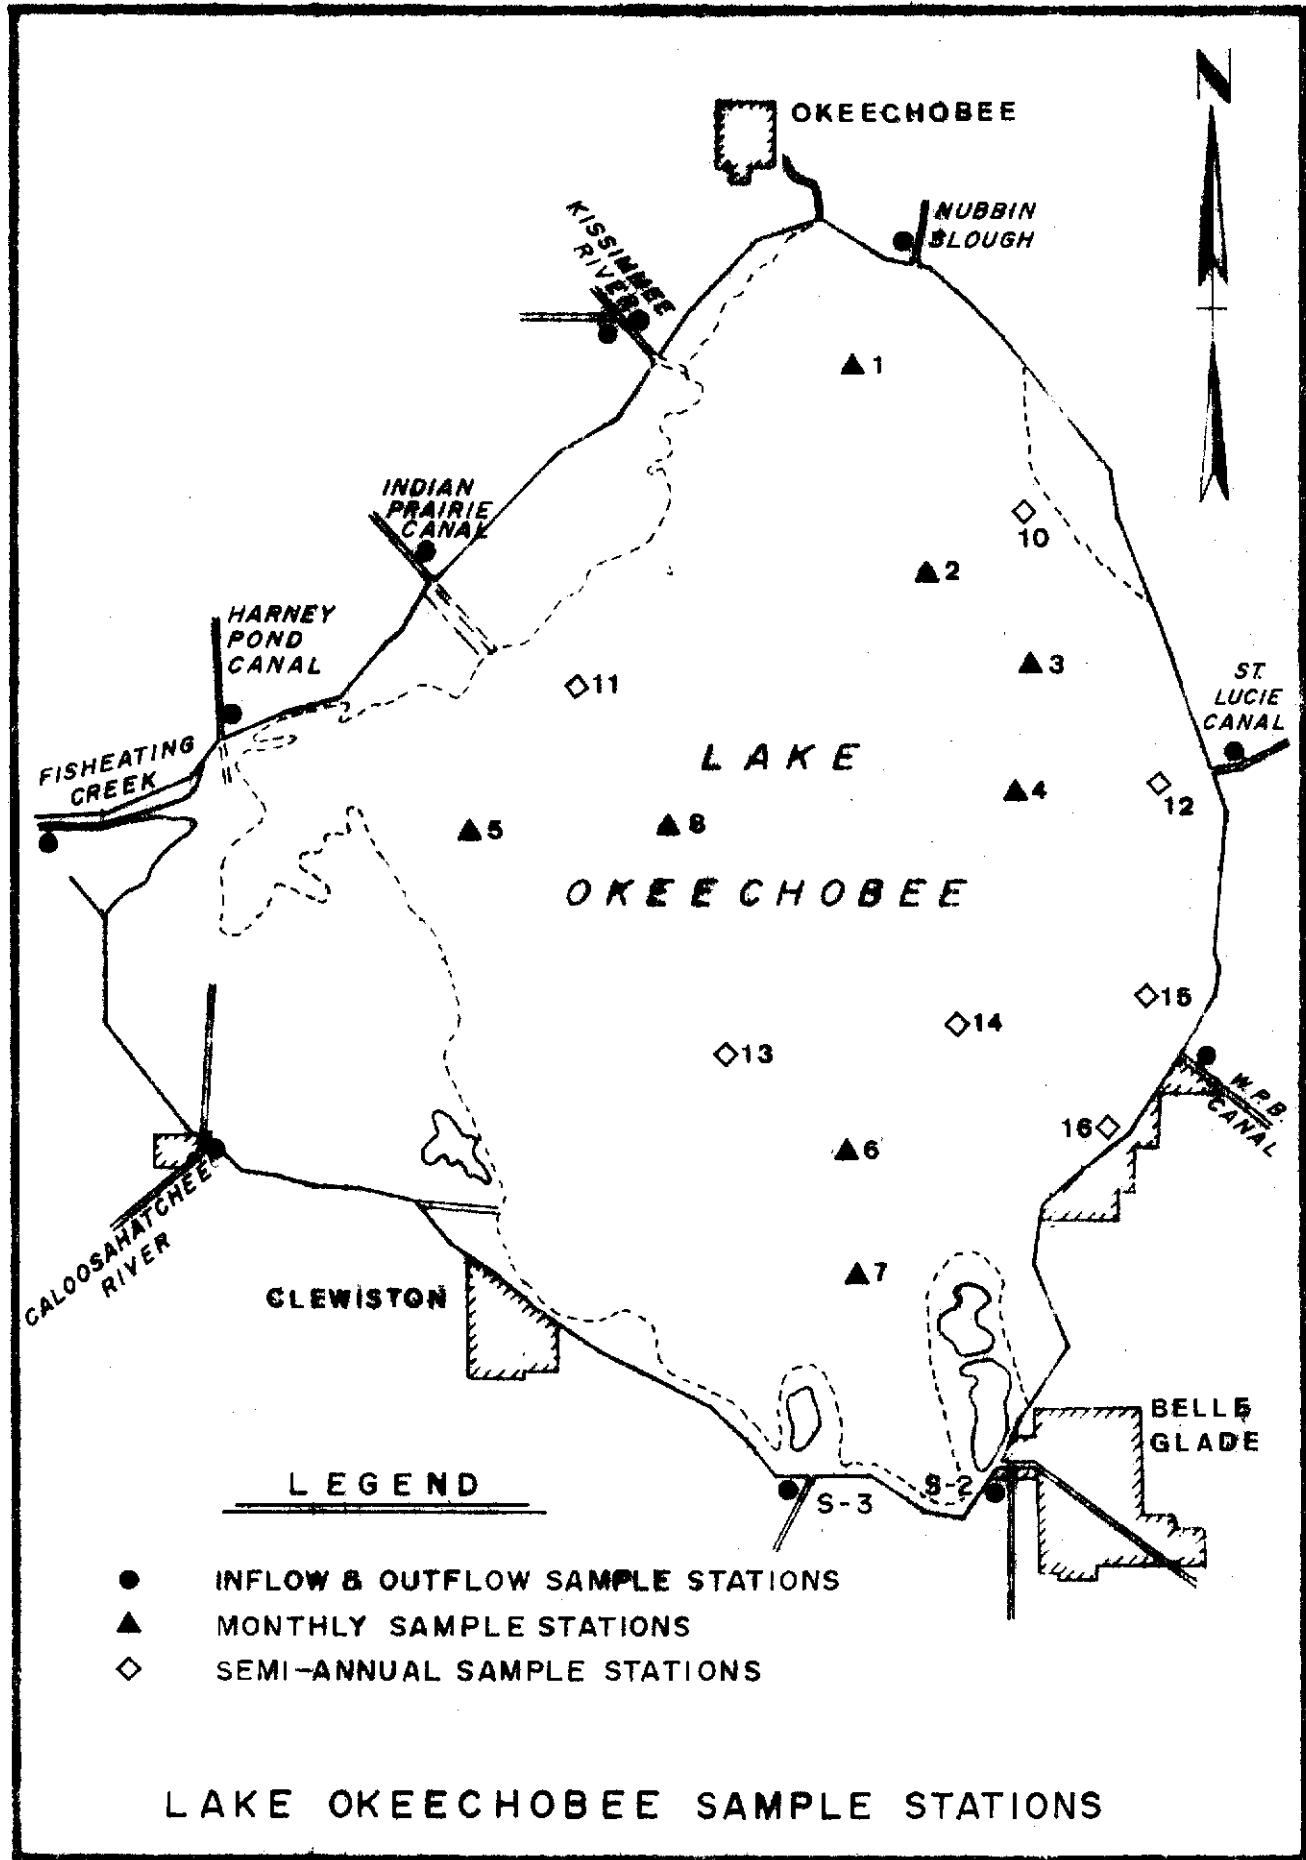

FIGURE 6

Figure 6 also shows the location of the sampling stations for the major inflows and outflows of Lake Okeechobee. During periods of high flows, May 1973 to November 1973, weekly chemistry samples were collected at the major inflows and outflows. Thereafter samples were collected at these stations every two weeks.

Chemistry Methods

Until June 1973, field data (dissolved oxygen, temperature, specific conductivity and pH) were recorded with a Yellow Springs Instrument Company model 54 D.O./Temp. probe, a Beckman Instruments Company model RB-3, Y147 conductivity meter and Beckman Instruments Company model 100901 field pH meter. After June 1973 all field data were collected with a Hydrolab[®] Surveyor II. Secchi disc readings were measured in centimeters using standard 8" disc.

Both surface and bottom water chemistry samples were collected for laboratory analysis at each Lake station with a 5 liter PVC Niskin sampler. The surface samples were collected from 0.5 meters below the surface. Bottom samples were taken at a depth of 0.5 meters above the bottom to prevent contamination of the sample with bottom sediments.

Dissolved nutrient and major anion samples were preserved by filtration through 0.45 micron membrane filters. Samples for major cation and trace metal analysis were also filtered and preserved with concentrated nitric acid (10 drops/100 ml). Unfiltered aliquots of samples were collected for total nutrient analysis. All samples were stored in polyethylene bottles on ice. The time between collection of samples and chemistry laboratory analysis varied between 1 and 2 weeks. In the laboratory samples were stored at 4°C in the dark.

No field data were collected at the major inflows and outflows. Surface chemistry samples were collected and stored unfiltered on ice for 12 to 24 hours until they arrived at the laboratory. They were then filtered as described for the Lake samples above.

The routine chemical analyses on each sample usually included the following parameters:

1. Dissolved nutrients (nitrate, nitrite, ammonia and ortho-phosphate)
2. Total phosphorus and total nitrogen
3. Major cations and anions (sodium, potassium, calcium, magnesium, chloride silicate, alkalinity and sulfate)
4. Trace metals (semi-annually during June and January)

The analytical chemistry methods used in this study were either recommended or approved by the Environmental Protection Agency or the American Public Health Association. Most analyses were performed on either a Technicon Industrial Systems II AutoAnalyzer or a Perkin Elmer Model 306 Atomic Absorption Spectrophotometer. Specific methodologies are shown in Table 1.

Biology Methods

Primary productivity estimates were made by the light and dark bottle method (Strickland and Parsons, 1968). Oxygen concentrations were determined in the field by the Azide modification of the Winkler titration method (Standard Methods, 13th Ed.). Duplicate bottles, suspended from floats, were incubated in situ for six hours at a depth of 22 cm. This depth was the minimum depth at which bottles could be placed and not have them break the surface during periods of rough water. Incubation was initiated between 0900 and 1100 hours. Daily productivities were calculated by multiplication of the average productivity rate for the six hour incubation period by the day length.

Two 250 - 300 ml aliquots of raw water were taken at a depth of 0.5 meters for phytoplankton analysis. One aliquot was refrigerated to allow later examination of live samples and the other was preserved for enumeration. Initially 4% formaldehyde was used as the preservative but from August 1973 to the present, Lugol's solution has been used.

Zinc,	Aqueous solution/No extraction	214 nm (U.V.) Air acetylene flame Standard burner head	Ref: same as above

A Palmer counting chamber was used to enumerate the preserved algae. The samples were mechanically shaken for a minimum of ten minutes to provide a homogeneous sample. The phytoplankton within 20 fields at 400 X magnification were counted on each of two separate slides. In enumeration, a colony and a filament were each counted as a single unit. The taxonomic keys which were used to identify the phytoplankton are: Prescott (1970), Smith (1950), Tiffany and Britton (1971), and Whitford and Schumacker (1969).

Benthic invertebrates were sampled using a standard Ekman dredge (15.2 cm x 15.2 cm). A total of four grabs were taken at each station to yield the standing crop for approximately 0.1 square meters. In November 1973, samples were also collected using a standard Peterson dredge at Stations 2 and 6. Samples were washed through a U. S. Standard Sieve, Series No. 20, preserved in 10% formaldehyde and returned to the laboratory for identification. Samples were again washed through a No. 20 sieve and organisms were separated from sediments and detritus using sugar flotation. Organisms were identified to species when possible.

Hydrology Data

Unless otherwise noted, the hydrological data used in this report were taken from unpublished monthly summary sheets prepared by the Jacksonville office of the U. S. Army Corps of Engineers. These summaries list the daily stage, rainfall rates, evaporation rates, discharges into the Lake and discharges out of the lake.

Due to alterations in the drainage patterns of Taylor Creek and Nubbin Slough which were not immediately reflected in the Corps' summaries, the discharge for Nubbin Slough/Taylor Creek basins were obtained directly from FCD hydrologic records.

Radar analysis of rainfall rates directly over Lake Okeechobee by the Experimental Meteorological Laboratory, National Oceanic and Atmospheric Agency,

Miami, Florida have shown significantly lower rates for the Lake than for the surrounding land area (Riebsame, et al., 1974). Since rainfall data in the Corps' summaries were taken from land based gauges around the Lake, the gauge data were reduced. Although the radar data indicated the rainfall data rates were up to 45% less over the Lake than as measured by land gauges during the summer months, a 20% reduction was applied to the data since the radar study involved only 45 days during the summer of 1973 and different meteorological conditions prevailed during the other months.

For calculation purposes the total rainfall inputs and evaporation losses were calculated based on the surface area of the Lake at the time of input or loss. These surface areas were taken from the stage/area table for the Lake prepared by the Corps of Engineers.

Loading rates of nitrogen and phosphorus to Lake Okeechobee were calculated for each inflow including rainfall. The results of chemical analyses at each major inflow were averaged over monthly intervals and applied to the total monthly flows. During periods of high flow, the chemistry averages were based on four data points, while during periods of low flow they were based on 1 or 2 data points. Loading rates for rainfall input were calculated based on average water quality of rainfall reported by Joyner (1972).

Monthly water budgets for the Lake were calculated to coincide with the intervals between routine water sampling of the Lake. These budgets itemized all inflows including rainfall. The outflows were only divided into evaporation losses and total surface discharge from the Lake. The monthly budgets were then summed over six and twelve month intervals to provide the water budget base necessary to calculate material budgets.

The material budgets used the previously calculated loading rates to estimate inputs. Losses of materials were calculated monthly from average lake water quality data and total outflows during the monthly intervals. Lake

storage of materials was based on average Lake water values of materials in question and total volume of the lake at the beginning and end of each budget period. Lake volumes were estimated from the same tables mentioned for Lake surface area. Materials budgets were calculated for six month periods to coincide with the wet (June through October) and dry (November through May) periods. These six month budgets were then summed to provide yearly budgets.

Statistical Analysis

Standard statistical techniques were used to calculate mean and standard deviation statistics for various parameters. When necessary these means were tested for statistical differences using the assumption that the variances were equal and known.

Linear regression analyses between parameters used the method of least squares. The slope of the calculated regression lines were tested to determine if they were significantly different from zero using the one tailed Student's "t" test. Coefficients of determination, r^2 , were calculated for the regression lines (where r is the estimated correlation coefficient).

Other Methods

Effective Wind Displacements, EDI, were calculated for each sampling date according to the method of Ayers,et al., (1958). Wind speed and direction data necessary for these calculations were obtained from the Clewiston Field Offices of the U. S. Army Corps of Engineers. Five to seven days of record (prior to the sampling date) from three anemometers were used in the calculations. The anemometers were located near Okeechobee City, Port Mayaca and Belle Glade. The calculated EDI values for each anemometer were then averaged to give a single EDI value for the Lake.

RESULTS

Limnetic Chemistry

The results for selected chemical parameters measured at Stations 1 through 8 for Lake Okeechobee from January 1973 to May 1974 are summarized in Table 2. This table shows the monthly mean surface and mean bottom values for temperature, dissolved oxygen (D.O.), Secchi disc readings, total phosphate, ortho-phosphate, total Kjeldahl nitrogen, nitrate, sodium, calcium, and chloride. The standard deviation of the means and number of analyses have also been included. The results of all field and laboratory analyses of samples collected from the Lake are listed in Appendix A.

Although Table 2 shows mean values for both surface and bottom samples, the difference between these means for any month is usually not significant. Only temperature and D.O. showed statistically significant differences using the Student's "t" test at the 90% significance level. The significant differences in temperature and D.O. may be due to the fact that all samples were collected during daylight hours and, therefore, reflect the effects of surface warming and biological oxygen production. The fact that the remaining parameters showed no significant stratification indicates that the Lake was well mixed vertically at all times of the year.

The mean values for major ions (sodium, calcium, and chloride) in Lake Okeechobee showed moderate variations with time. For all three ions the lowest mean values were recorded in October 1973, which was also the month of highest Lake stage. The higher mean values tended to occur during periods of low Lake stage, such as May and June of 1973 and April 1974. During periods of rising Lake level the standard deviations of these means also increased indicating greater variability in the data for those months.

\bar{X} = mean values S = standard deviation N = number of data points

Variations with time of the monthly mean values of several parameters in Table 2 and some additional parameters are illustrated graphically in Figures 7 and 8. The lines between successive values in the figures are not intended to represent the rate of change for each value but have only been included to facilitate reading the graphs.

A summary of the field data excluding pH values is shown as monthly means for all eight lake stations in Figure 7. The pH values measured for Lake Okeechobee varied only slightly between 8.2 and 8.4 and therefore were not included in Figure 7.

The mean Secchi disc readings in Figure 7 varied from less than 30 cm in April 1974 to more than 100 cm in August 1973. As a measure of water clarity the Secchi disc readings indicate clearer water in the summer months than in the winter months.

The average water temperature extremes measured during the study was 15°C. The highest average water temperature (29.5°C) was measured during August 1973. The lowest temperatures measured occurred in January of 1973 when the mean water temperature dropped to 14.1°C. The surface temperatures as shown in Figure 7 were higher than bottom values although the difference was usually less than 1°C. The greatest difference between surface and bottom temperatures, 2.5°C, occurred in March 1973.

Figure 7 also shows the mean dissolved oxygen (D.O.) concentration for surface and bottom samples. The D.O. generally tended to be at or near saturation with respect to temperature and varies inversely to temperature. The highest D.O. measured, 9.7 mg/l, occurred in January 1973 when the lowest temperature occurred. The lowest average D.O. measured was 6.9 mg/l in July 1973 one month before the highest temperature. Unfortunately, no oxygen values were available for August 1973. As with temperature, the D.O. curves show higher surface

LAKE OKEECHOBEE MEAN VALUES FOR
SECCHI DEPTH, TEMPERATURES, D.O. AND SPECIFIC CONDUCTIVITY
JAN. 1973 TO JULY 1974

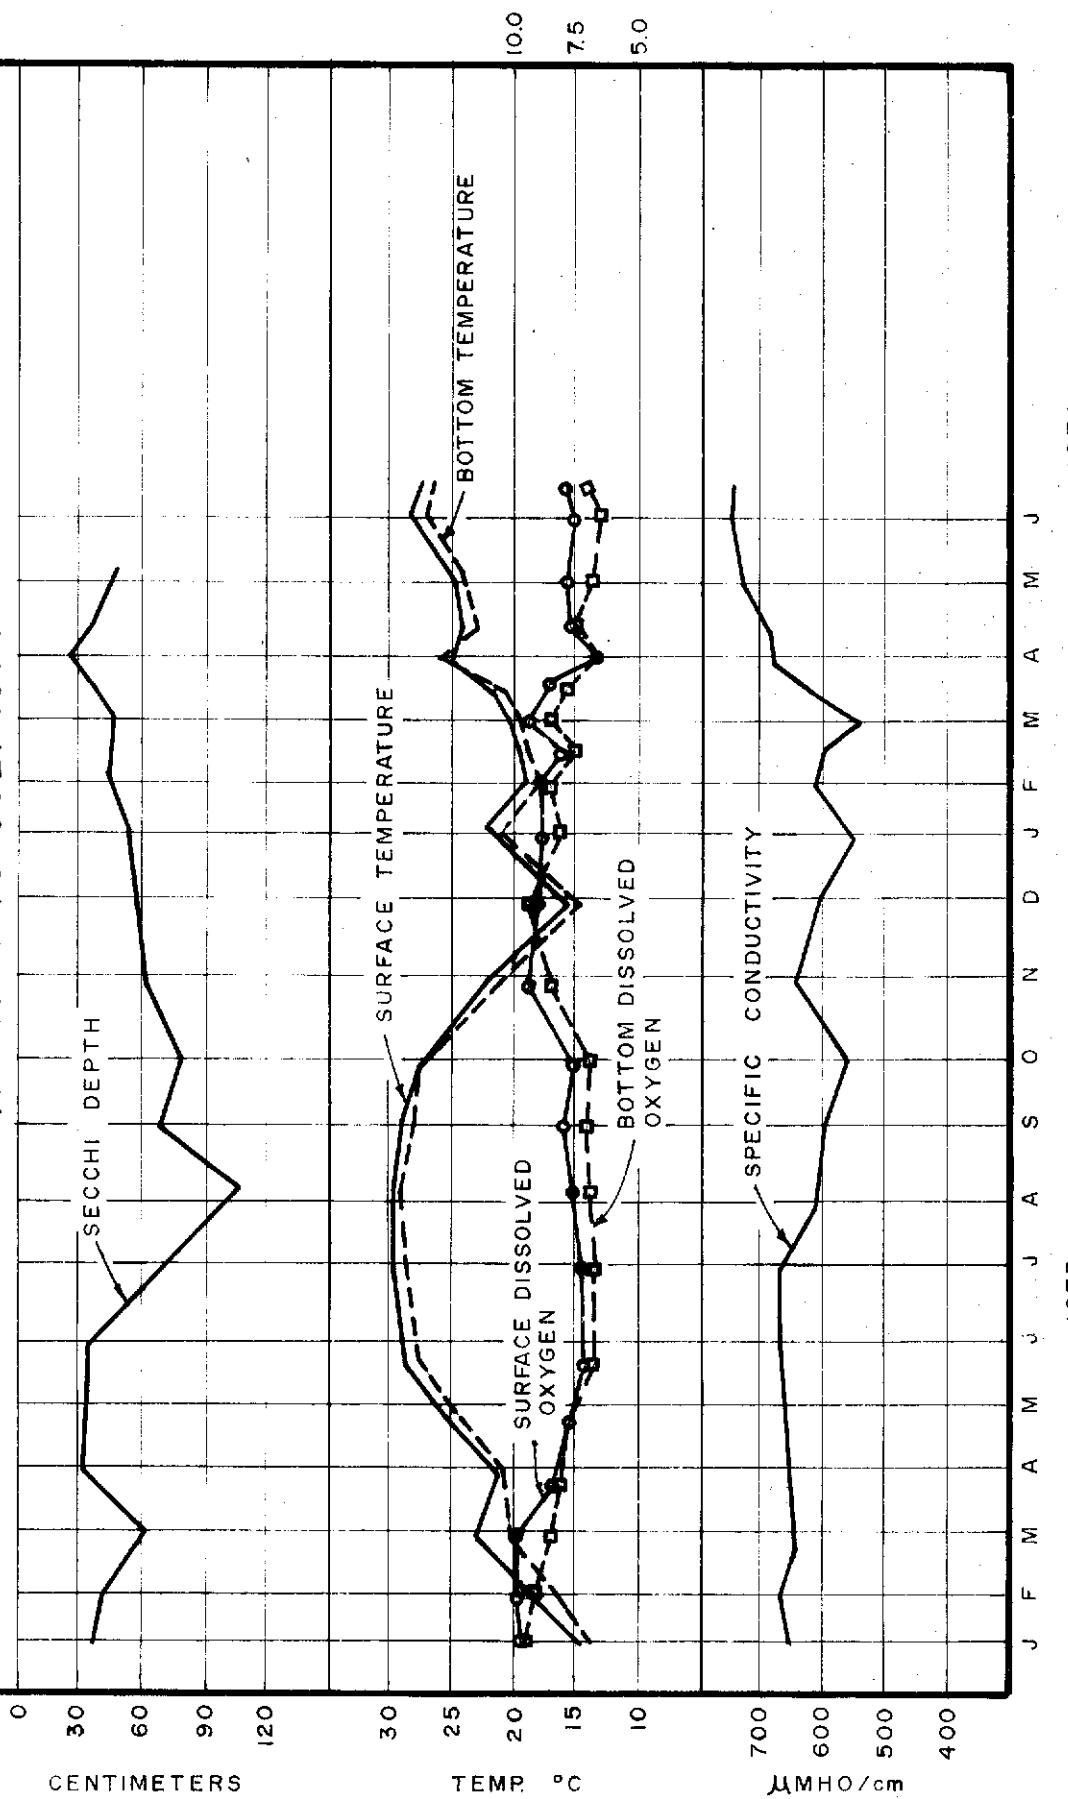

FIGURE 7

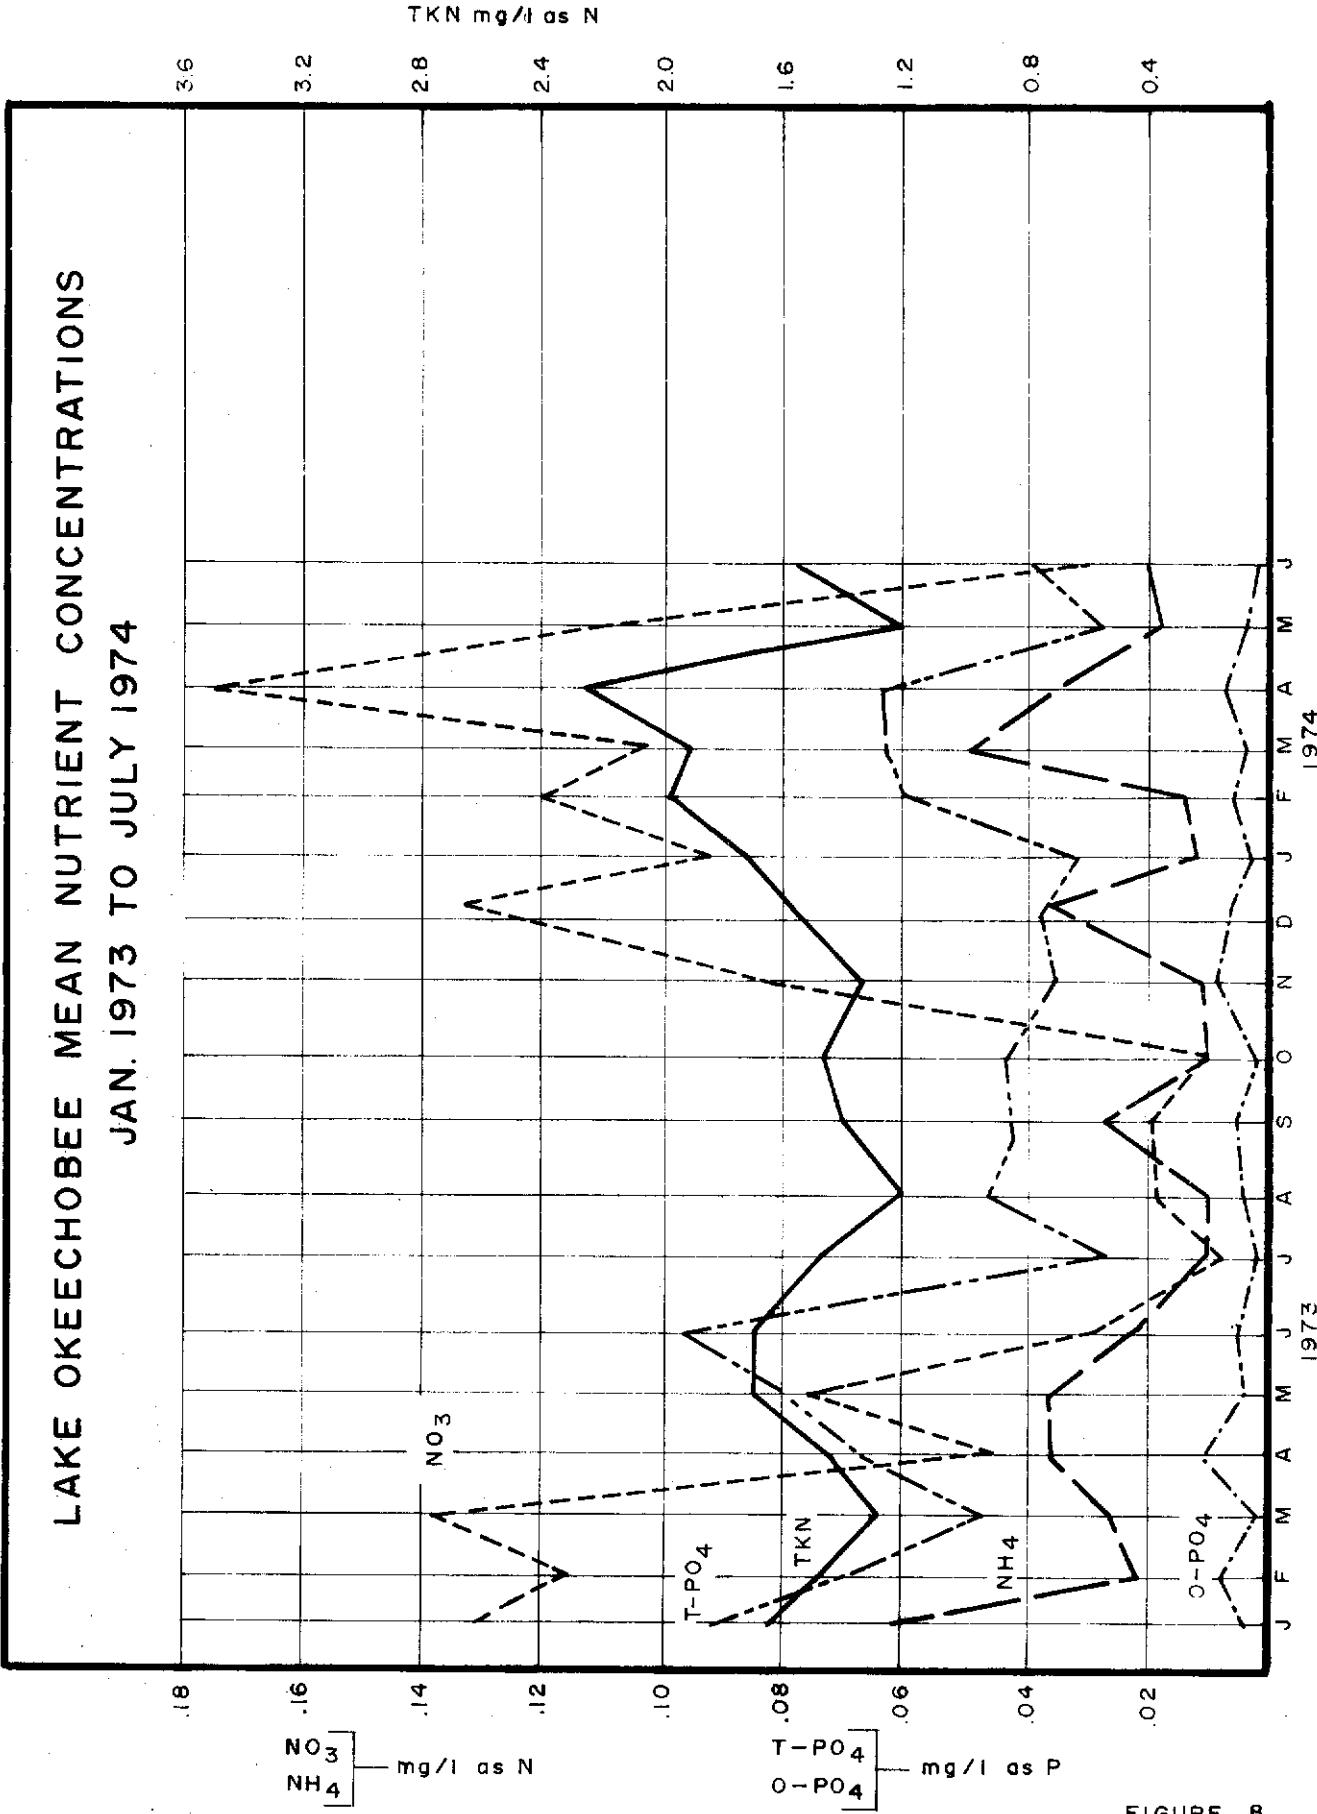

FIGURE 8

values than bottom values. There were two exceptions to this trend. In November 1973 the average surface dissolved oxygen was several tenths of a mg/l less than the average bottom value. There was a temperature inversion in March 1974 when surface temperatures were slightly lower than bottom temperatures.

The plot of average specific conductivity for each sampling date (Figure 7) indicates that the highest value, 740 $\mu\text{mhos}/\text{cm}$, occurred in June 1974 while the lowest value, 550 $\mu\text{mho}/\text{cm}$, occurred in March 1974. Specific conductivity of freshwater is a general measure of dissolved solids, although there are no fixed relationships between the two. Since this study included analysis of major ions, the discussion of dissolved solids will be based on the ionic analysis rather than specific conductivity.

The average concentration by month of the major nutrients, phosphorus and nitrogen, are shown in Figure 8. Both total phosphate ($T-\text{PO}_4$) and inorganic ortho-phosphate (o-PO_4) are reported as mg/l phosphorus, while total Kjeldahl nitrogen (TKN), nitrate (NO_3) and ammonium (NH_4) are reported as mg/l nitrogen. The total phosphate values include inorganic, dissolved organic, and particulate phosphorus fractions. TKN values include free ammonium as well as dissolved organic and particulate nitrogen but do not include nitrate or nitrite. Nitrite values are generally very low and have not been included. It should be noted that the concentration scale for TKN is 1/20 of the scale for the other species shown. The values shown in Figure 8 are mean values of results from both surface and bottom samples.

All parameters plotted in Figure 8 show minimum values during the late summer and fall of 1973. Nitrate concentrations had the greatest variation ranging from less than 0.01 mg/l to almost 0.20 mg/l. There was a constant

drop in average nitrate nitrogen in the Lake from March 1973 to July 1973. From July to October 1973 the average concentrations of nitrate nitrogen were less than 0.02 mg/l and many individual values were below the analytical limits of detection which was 0.004 mg/l. The values for nitrate increased almost an order of magnitude from October to November 1973. Relatively high levels of nitrate persisted in the Lake until May 1974. The data for 1974 is incomplete at this time but there appears to be evidence for another period of low nitrate values during the summer of 1974.

The other nitrogen species in Figure 8 show much less variation. TKN values were lowest in August 1973 and highest during April 1974. Since the TKN values seem to parallel the nitrate values, the large variations in nitrate nitrogen do not appear to be due to conversion of nitrogen from one species to another.

Ammonia values also seem to parallel TKN but much of the variation in the ammonia has been lost because many results for ammonia analysis were below the 0.01 mg/l limits of detection.

Total phosphate values in Figure 8 show maximum values during both the spring of 1973 and 1974. This pattern was similar to that of the TKN although the relative magnitude of the peaks was reversed. Total phosphate showed the higher peak values in the spring of 1973 while the higher TKN values occurred in the spring of 1974.

It is difficult to know what pattern the ortho-phosphate species followed because there is relatively little variation in the ortho-phosphate values. Many of the ortho-phosphate analyses were below the analytical limits of sensitivity which were normally 0.002 mg/l P. Since the true variation in ortho-phosphate values cannot be shown there is no way to assess the relationship between ortho-phosphate and total phosphate.

The seasonal means for selected chemical parameters at sampling Stations 1 through 8 are summarized in Tables 3 and 4. Mean values for the same parameters have also been calculated for the entire study period and are shown in Table 5. All the means except Secchi disc readings have been calculated using both surface and bottom values.

Comparison of Table 3 and Table 4 indicates that the concentrations of nitrogen in the Lake were lower during the wet season (May to November) than during the dry season (November to May). The average nitrate concentration showed the greatest difference between wet and dry seasons.

Among the individual stations, the greatest decreases in nitrate concentrations occurred at Stations 4, 6, 7, and 8. The remaining four stations also had decreased nitrate values during the summer months, but the differences were much less.

TKN values were consistently lower in the wet season than in the dry season but the difference between seasonal averages was not as great as for nitrate.

No significant variations occurred in the ortho-phosphate values. The total phosphate values in Tables 3 and 4 do not show consistent differences from wet to dry seasons. Stations 1, 2, 7, and 8 had higher average total phosphate concentrations during the wet months in comparison to the dry months. The remaining stations showed slightly reduced values for the wet period in comparison to the dry period.

Generally, the major ions show higher values during the May to November period than during the November to May period. Although the months from May to November are months of greatest rainfall and inflow into the Lake, the stages during this time are low with a tendency to increase until the dry season

\bar{X} = mean value S = standard deviation N = number of data points

(November to May) when they begin to fall again. Thus, the major ions tend to be most concentrated during the period of low and rising lake stages. The only exceptions to this are Stations 1 and 5 which show the opposite trend. These stations are the closest to major inflows into the lake and are rapidly affected by the reduced ionic concentrations of these inflows.

The average water clarity (Secchi disc reading) at each station showed consistent seasonal differences. Every station recorded greater Secchi disc readings during the wet period as compared to the dry period.

The seasonal means for each station presented in Tables 3 and 4 indicate that the seasonal variation in water chemistry data based on Lake-wide averages as shown in Figures 7 and 8 are also evident at the individual stations.

The means of all sampling data for Stations 1 through 8 shown in Table 5 indicate that significant areal variations in water chemistry data exist within Lake Okeechobee.

Stations 5 and 7 had the best water clarity based on Secchi disc readings. The average Secchi disc reading at these two stations was almost double those at the other stations. These two stations also had the lowest average total phosphate concentrations. Stations 4 and 8 had the poorest water clarity and highest total phosphate concentrations. These two stations also had moderately high average nitrate levels. The highest nitrate values were recorded at Stations 6 and 7 with the lowest values at Stations 1 and 5. Stations 1 and 5 also had the lowest average major ion concentrations.

Trace Metals

The results of trace metal analysis on water samples collected from Lake Okeechobee in June 1974 are shown in Table 6. The analysis for trace metals on samples collected in January 1973 has been omitted due to incomplete data.

All results shown in Table 6, except for iron, are dissolved trace metals. The iron analyses were performed on unfiltered sample aliquots which had first been digested with hot hydrochloric acid.

The results indicate relatively low levels of heavy metals except for Strontium. The high Strontium concentrations are not unexpected due to the relatively high calcium and magnesium levels in the Lake. There does not appear to be any significant variation in trace metal concentrations from station to station. Total iron and to some extent copper were more concentrated in the bottom samples in comparison to surface samples. This may be due to increased particulate matter in the bottom samples.

Primary Productivity

Primary productivity is the rate at which carbon is fixed by the primary producers. In Lake Okeechobee this involves mainly phytoplankton. Elements which are generally measured are gross primary productivity, net primary productivity and respiration. Gross primary productivity is the total amount of carbon fixed during photosynthesis. Net primary productivity is the amount of carbon fixed after allowances have been made for losses due to respiration and other metabolic processes occurring in the plant cell during photosynthesis.

Monthly average primary productivities are shown in Figure 9. Monthly primary productivities by station are shown in Figure 10 and listed in Table 7. In Lake Okeechobee the net primary productivity was essentially the same as the gross primary productivity (Figures 9 and 10). The instances in which the net productivity was larger than the gross productivity may be accounted for by the insensitivity of the Winkler oxygen method. Respiration generally represented less than 15% of the gross primary productivity. In the discussion which follows "productivity" will be used to mean gross primary productivity, ergo, net primary productivity.

Three peaks in average primary productivity were recorded in 1973: March 2600 mg C/m³/day; June, 2200 mg C/m³/day; and September, 2800 mg C/m³/day. The fall peak (September) in primary productivity was highest, followed by the spring (March) and summer (June) peaks.

The productivity records of the individual stations (Figure 10) indicate significant areal variation. The data for the spring peak is incomplete so that the timing and magnitude of this peak is uncertain. Stations 1 and 4 had productivities of 1700 and 3500 mg C/m³/day, respectively, in March. In April, Stations 5 and 6 had values of 2400 and 1600 mg C/m³/day, respectively.

Smaller peaks in productivity were observed in June at Stations 5 and 6. The productivity at Station 6 was 3200 mg C/m³/day and 1200 mg C/m³/day at Station 5.

The highest productivities of 1973 were recorded in August, September and October. Maximum productivity occurred at different times in different parts of the Lake. Station 1 showed a gradual increase in productivity from April to a peak (3700 mg C/m³/day) in August, then a gradual decrease through November. Station 6 showed an abrupt increase in productivity from July to a maximum (3700 mg C/m³/day) in September, then an abrupt drop to a minimum in November. Station 5 showed a less abrupt increase from July to a peak productivity (2700 mg C/m³/day) in October, then a drop in November. From the shape of the curve, it appears that the true peak at Station 5 may have occurred sometime late in September. Logistical problems prevented primary productivity measurements at Station 4 from July through October. However, productivity measurements were taken at Station 4 in November and this station had the highest productivity (2200 mg C/m³/day) for that month. Logistical problems also prohibited measurements in December 1973 at all stations.

During 1973, the highest productivity, 3700 mg C/m³/day, was recorded at Station 1 in August and Station 6 in September. The lowest productivity, 300 mg C/m³/day, was recorded at Station 5 in July. The average primary productivity for the Lake, for all productivity stations in 1973, was 1864 mg C/m /day.

Certain stations were generally more productive than others. The average productivities for the stations for 1973 were as follows: Station 1, 2300 mg C/m³/day; Station 4, 2200 mg C/m³/day; Station 6, 1700 mg C/m³/day; and Station 5, 1400 mg C/m³/day. The north and north-central stations (1 and 4, respectively) were the most productive. The south-central station (6) was on an average slightly less productive than the north-central station. The westernmost station (5) was the least productive of all the sample stations.

Algal Populations

A listing of the algae observed in Lake Okeechobee is given in Table 8. The distribution of the significant algal groups is shown in Figure 11.

The blue-green algae (Cyanophyta) were the dominant algae of Lake Okeechobee. The most frequently occurring blue-greens were Oscillatoria sp., Lyngbya contorta, Microcystis aeruginosa, and Microcystis incerta. The filamentous Oscillatoria sp. and L. contorta were the dominant blue-green algae at most sites throughout the year. M. aeruginosa, the massive buoyant colonial blue-green, formed thick scums 2-5 mm thick, on the surface of the water in late fall.

Stations 1 and 5 had the highest average percentage of blue-green algae (Figure 11) and these stations also had a much more diverse blue-green algal flora than did the other lake stations.

The most common green algae (Chlorophyta) were the unicellular flagellated types, including Chlamydomonas sp., Carteria cordiformis, Chlorogonium sp. and

AVERAGE PHYTOPLANKTON COMPOSITION BY STATION

several, as yet unidentified, species. These algae dominated the spring pulse which was first observed at Stations 3 and 4. The flagellated unicellular types of green algae were more numerous and generally more common than desmid types throughout the Lake.

Desmids accounted for a relatively smaller proportion of the green algae population. Observed most frequently were several species of Closterium, Pediastrum, Scenedesmus, and Staurastrum. They were found most frequently in samples taken at Stations 1 and 5.

Green algae made up a larger portion of the algal populations at Stations 3, 6, and 7 than at the other Lake Stations (Figure 11).

Diatoms (Chrysophyta) were present in relatively small numbers throughout the year. The most common representatives, Coscinodiscus sp., Melosira sp., Tabellaria sp., Gyrosigma sp., Navicula sp., Amphora sp., and Synedra sp., were most important in the winter and spring and were absent in the summer. The diatom flora was generally more numerous and diverse at Stations 1, 5, and 7 near the periphery of the Lake.

Only two Dinoflagellate species, Ceratium hirundinella and Glenodinium gymnodinium, were observed in Lake Okeechobee. C. hirundinella was observed mainly at Station 5. G. gymnodinium was observed once in live samples collected during non-routine sampling in the north and north-central part of the Lake.

The euglenoids (Euglenophyta) made up a very small part of the Lake phytoplankton, but may be of particular significance. The following euglenoids were observed: Euglena acus, E. gracilis, E. spiroides, E. viridis, Phacus torta, P. triquetus and Trachelomonas volvocina. These organisms were present at Stations 1 and 5 in June, Station 1 in September, Station 7 in October, and Stations 2 and 6 in November. Euglenoids were generally found during periods of

peak discharge into the Lake and their presence may be linked to high nutrient inputs.

Seasonal Phytoplankton Variation

The seasonal variation in average phytoplankton densities and compositions are shown in Figure 12. Table 9 lists the phytoplankton densities by month. Appendix C shows the phytoplankton density and composition by station for each sampling date.

Two pronounced maxima in phytoplankton densities were observed, one in the spring and one in the fall. Changes in phytoplankton populations from January to June 1973 were abrupt and dramatic. Phytoplankton densities nearly doubled between February and March. The peak in phytoplankton densities in March, April and May constituted the spring pulse. Succession of algal groups was apparent during this period. The increase in phytoplankton in March was due primarily to the increase in the number of small, flagellated, unicellular, green algae (Chlorophyta). Green algae were succeeded in April by diatoms (Chrysophyta) and large populations of filamentous blue-green algae (Cyanophyta). Decreases in blue-green algae and diatom populations accounted for the overall decline in phytoplankton populations in May. An increase in green algae in May made the decline less acute. In June, the number of phytoplankton dropped dramatically to values of less than 1/3 of the maximum values observed in April.

The spring pulse began abruptly in March and ended abruptly in June, whereas the fall pulse was marked by a gradual increase in numbers beginning in July, a peak in September, and a gradual decline through December. The increase in phytoplankton densities during the fall pulse was not as great as during the spring and was due mainly to increases in the population of blue-green algae. Initially, most of the blue-green algae were filamentous, but later a colonial blue-green

**Sample lost

algae became dominant. This shift to a colonial blue-green population caused some sampling difficulties. The buoyant colonial blue-greens formed a surface scum which persisted in much of the Lake from September through December, and in November, covered all Stations except 1 and 5. Because samples were taken at 0.5 m, the reported phytoplankton numbers and per cent composition may not be representative of the conditions which existed in the surface waters. Beneath the surface scum was a population of small green flagellates, which comprised a large percentage of green algae reported in the fall of 1973. The observed increase in green algae from September through November may indeed represent a true shift in algal populations. The blue-green algae, although more obvious, may not have comprised a significant proportion of the overall algal population.

Figure 13 indicates significant areal variation in phytoplankton densities by month at Stations 1, 4, 5, and 6. Station 1 had relatively constant phytoplankton densities, with a major peak in algal numbers occurring in July and minor peaks occurring in May and October. The peaks in May and July were due mainly to increases in blue-green algae, whereas the peak in October was due to green algae.

Peaks in algal numbers at Station 4 occurred in March, May and August. The major peaks, March and May, were dominated by small flagellated green algae, and filamentous blue-green algae, respectively. The peak in August was due completely to increases in blue-green algae.

At Station 5, minor peaks were recorded in April and June, with a major peak occurring in October. The increase in phytoplankton numbers from July to a peak in October was due to an increase in the number of blue-green algae. The number of green algae during this period was relatively large and constant.

Major and minor peaks in algal numbers at Station 6 occurred in May and September, respectively. Both were due to increases in blue-green algae

populations. This station had the highest average green algae population of any productivity station.

The range in Lake average phytoplankton densities was 4000 to 12000 phytoplankton units/ml in July and April, respectively. Using individual station data, the range was from zero at Station 7 in August, to 24000 phytoplankton units/ml at Station 3 in March.

Benthic Invertebrates

A description of the bottom sediments collected during the benthic sampling at each station is presented below.

<u>Station</u>	<u>Bottom Types</u>
1	Sand, some mud
2	Sand, mud, shell, some marl
3	Mud, some shell, some detritus
4	Mud, some shell
5	Sand, some shell, some detritus
6	Marl, pockets of mud
7	Peat, shell, rock, some marl
8	Sand, mud, some detritus

The results of benthic sampling appear in Table 10. The most common benthic invertebrates were oligochaetes, the amphipod Gammarus fasciatus, and the chironomid Pentaneurini sp. The highest number of organisms, $2562/m^2$, was collected in July at Station 7. The lowest was $50/m^2$ at Station 2 in February.

Diversity Indices (Shannon and Weaver, 1963) were calculated for each station. Stations were ranked in order of descending average diversity indices as follows: 3, 4, 1, 2, 7, 8, 5, and 6. Mud bottoms were most productive, followed by sand, peat, and marl.

It is interesting to note that the amphipod, Apelisa tenuicornis and the isopod, Sphaeroma terebrans (organisms also found in brackish water [Pennak, 1953]),

10

BASELINE MONITORING OF FALCON CREEK IN FARM LAKE, OKLAHOMA IN 1973

*P = Peterson Prejudice
L = Likert Prejudice

were found at Station 6. Also of interest is the larger concentration of Corbicula leana at the southernmost station. This clam is common in the agricultural canals south of Lake Okeechobee (Marshall, 1972, unpublished data).

Loading Calculations

The total discharge, average water quality and material loadings of major inflows to Lake Okeechobee are given in Table 11. The percentage figures for both discharge and loading data are the percentages of total water or material attributed to each inflow. The average concentration of nitrogen, phosphorus, chloride and calcium for each inflow was calculated by dividing the total element input by the total water input. The chemistry data for all major inflows and outflows of the Lake can be found in Appendix B.

Rainfall and the Kissimmee River were the largest contributors of water to Lake Okeechobee during the year from May 1973 to May 1974. The rainfall rates were lower than those reported in the past since they represent corrected gauge data as described previously. The Kissimmee River discharge was somewhat less than the previous 10 year average of 1,177,000 AF/year. Pumpage rates at S-2 and S-3 were also below the six year (1963-1969) average rates of 218,000 AF/year and 101,000 AF/year, respectively. Since 1973 was the first year that Nubbin Slough had discharged the combined Taylor Creek/Nubbin Slough drainage basin, it is impossible to determine if it was above or below normal.

Table 11 shows that the agricultural canals had the highest concentration of total nitrogen of all inflows to the Lake. Their nitrogen loadings represented 32% of the total of all inflows despite the fact that they contributed only 9% of the water. Harney Pond Canal and Indian Prairie Canal also had high nitrogen concentrations but their flows were too low for them to cause high loadings to the Lake. All other inflows had total nitrogen concentrations below the average

Lake concentrations. Both rainfall and the Kissimmee River contributed a high percentage of the total nitrogen loading to the Lake because of large water volume input rather than high concentrations of total nitrogen.

The average total phosphate concentration in Nubbin Slough was more than 10 times that of the Lake average. Thus, even though this inflow contributed only 7% of the water to the Lake during 1973-1974, it was responsible for 39% of the total phosphate. Harney Pond Canal and Indian Prairie Canal also had high average total phosphate levels. The discharge rate for Harney Pond Canal was high enough in this case to produce 13% of the total phosphate input. Although the agricultural canals had moderately high phosphate levels, their contribution to the total loadings was relatively minor. As in the case with nitrogen, the largest water inputs (Kissimmee River and rainfall) also were significant sources of total phosphate because of high inflow rates, rather than high concentration levels.

Except for the agricultural canals, all inflows to the Lake had lower major ion concentrations, as measured by the chloride and calcium values in Table 11, than existed within the Lake. The major contributors of dissolved salts to the Lake were the agricultural canals with well over 50% of the total input. Again, due to the high percentage of water input, the Kissimmee River was the second largest contributor of dissolved salts even though its concentration values were well below those of the Lake.

The monthly loading rates of nitrogen and phosphorus to Lake Okeechobee by the Kissimmee River, Nubbin Slough, agricultural canals, and rainfall are shown in Figures 14 through 17, respectively. These inflows represent over 80% of the total nitrogen and total phosphorus discharged into the Lake from May 1973

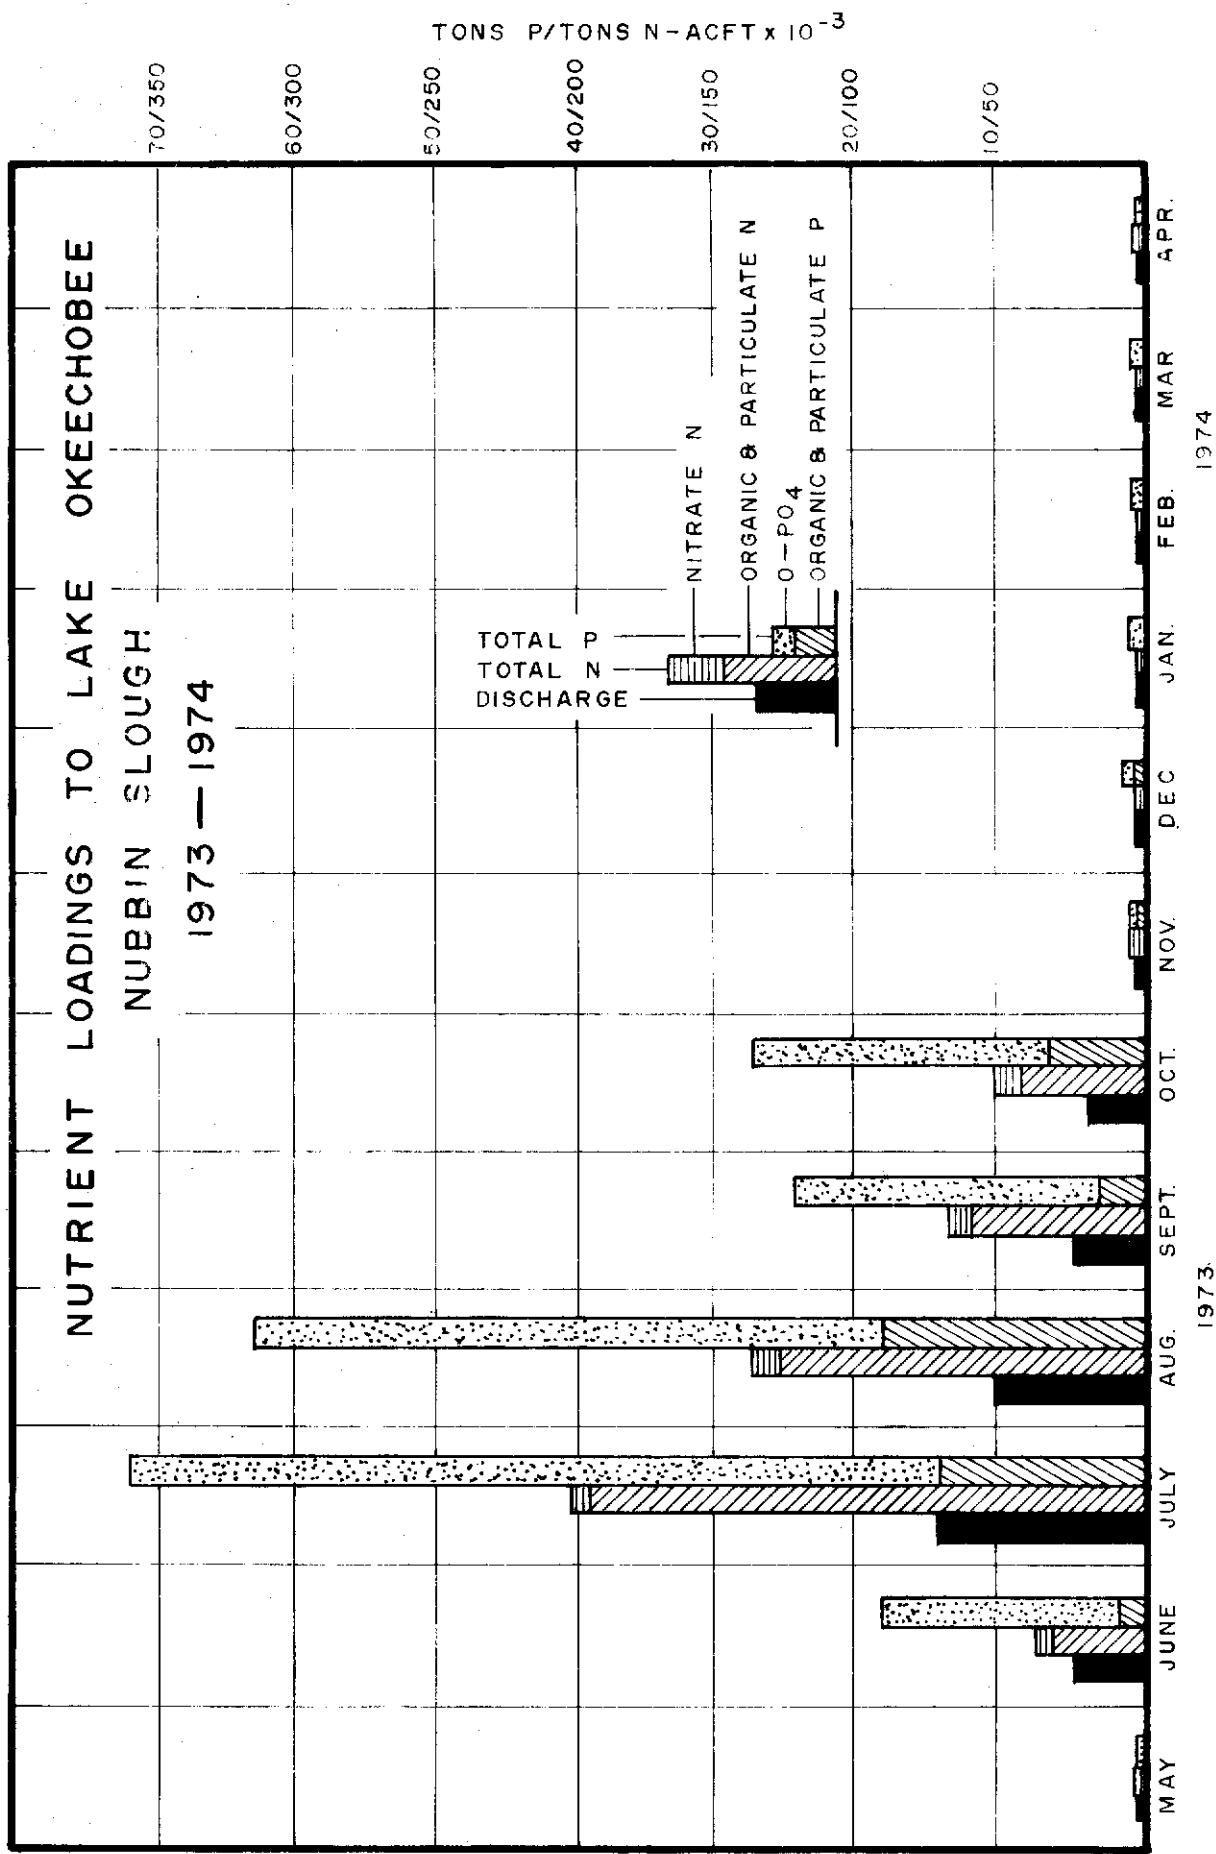

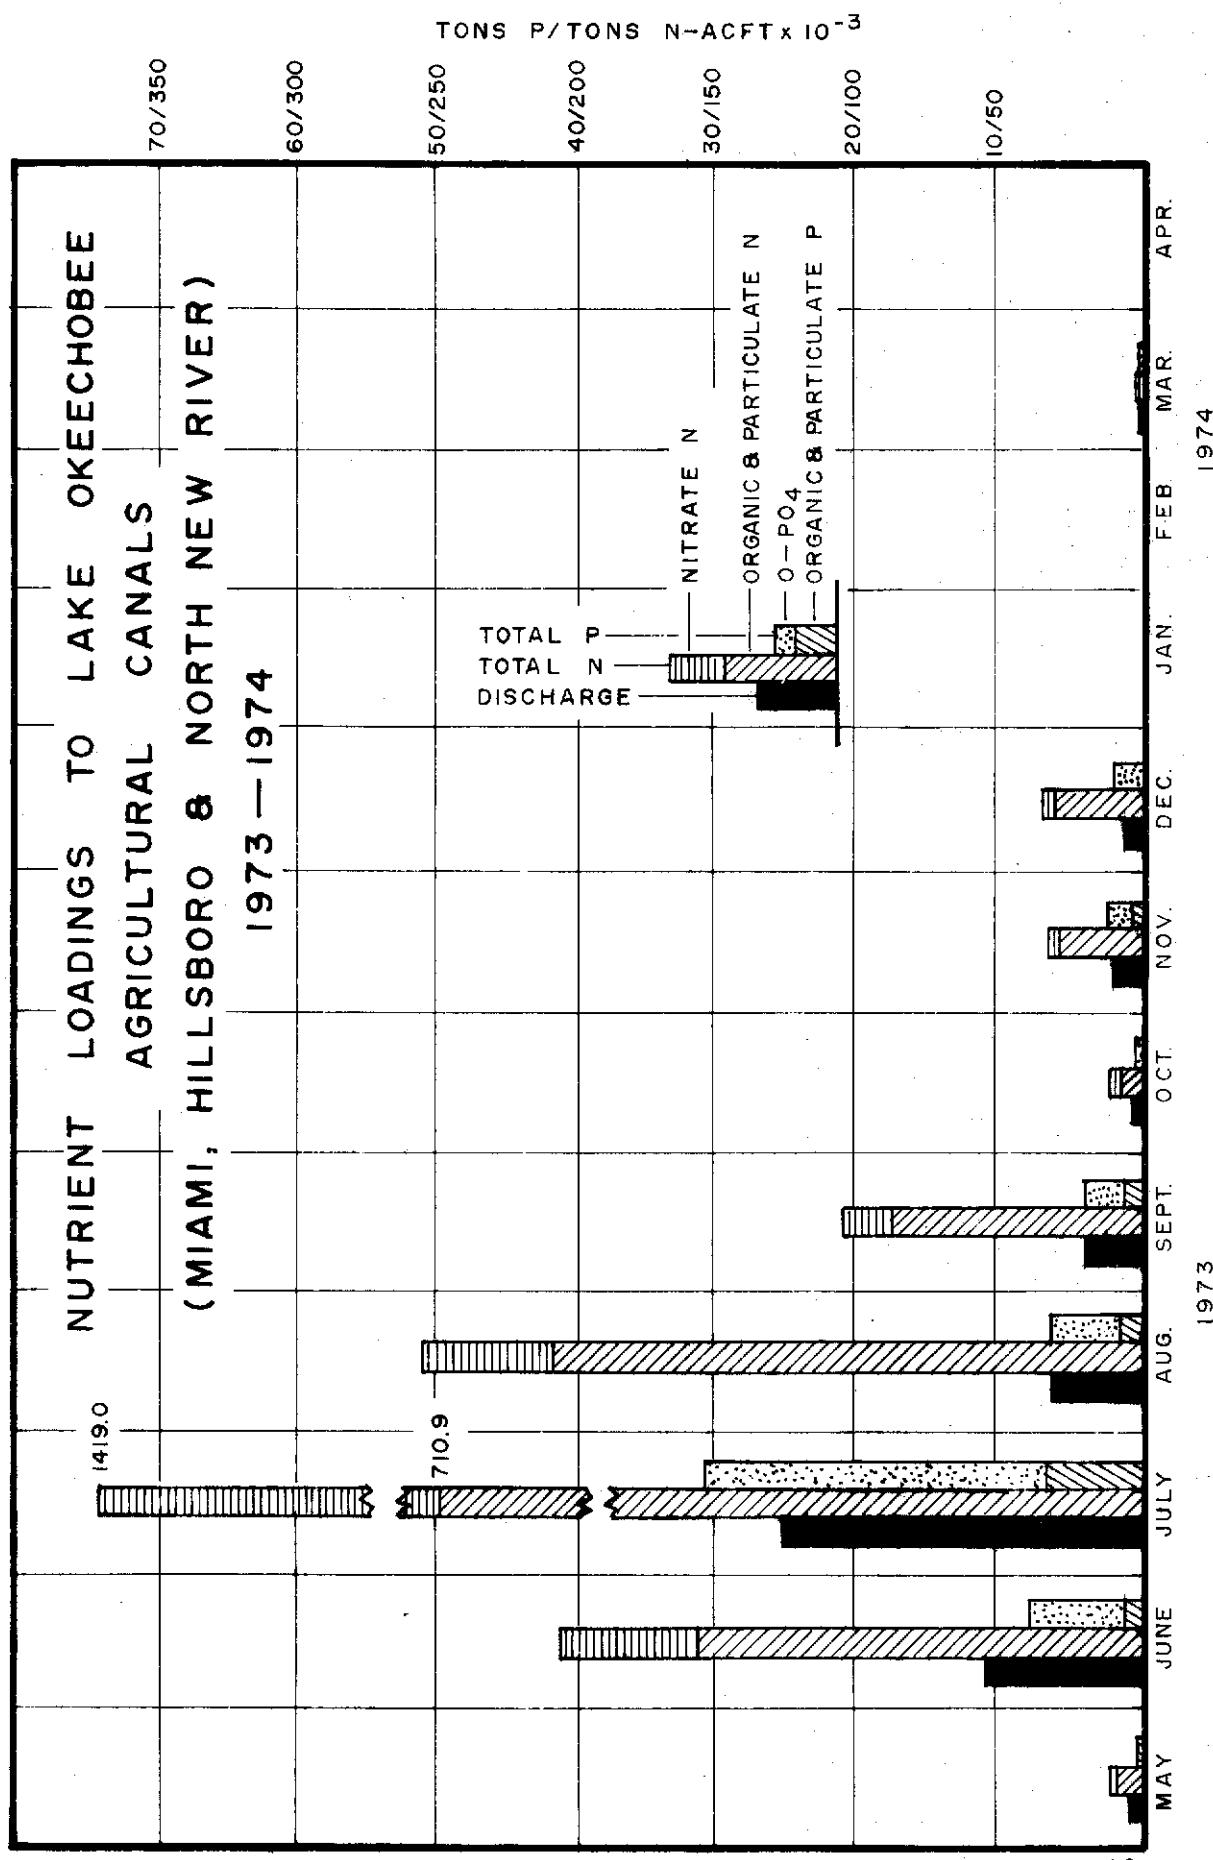

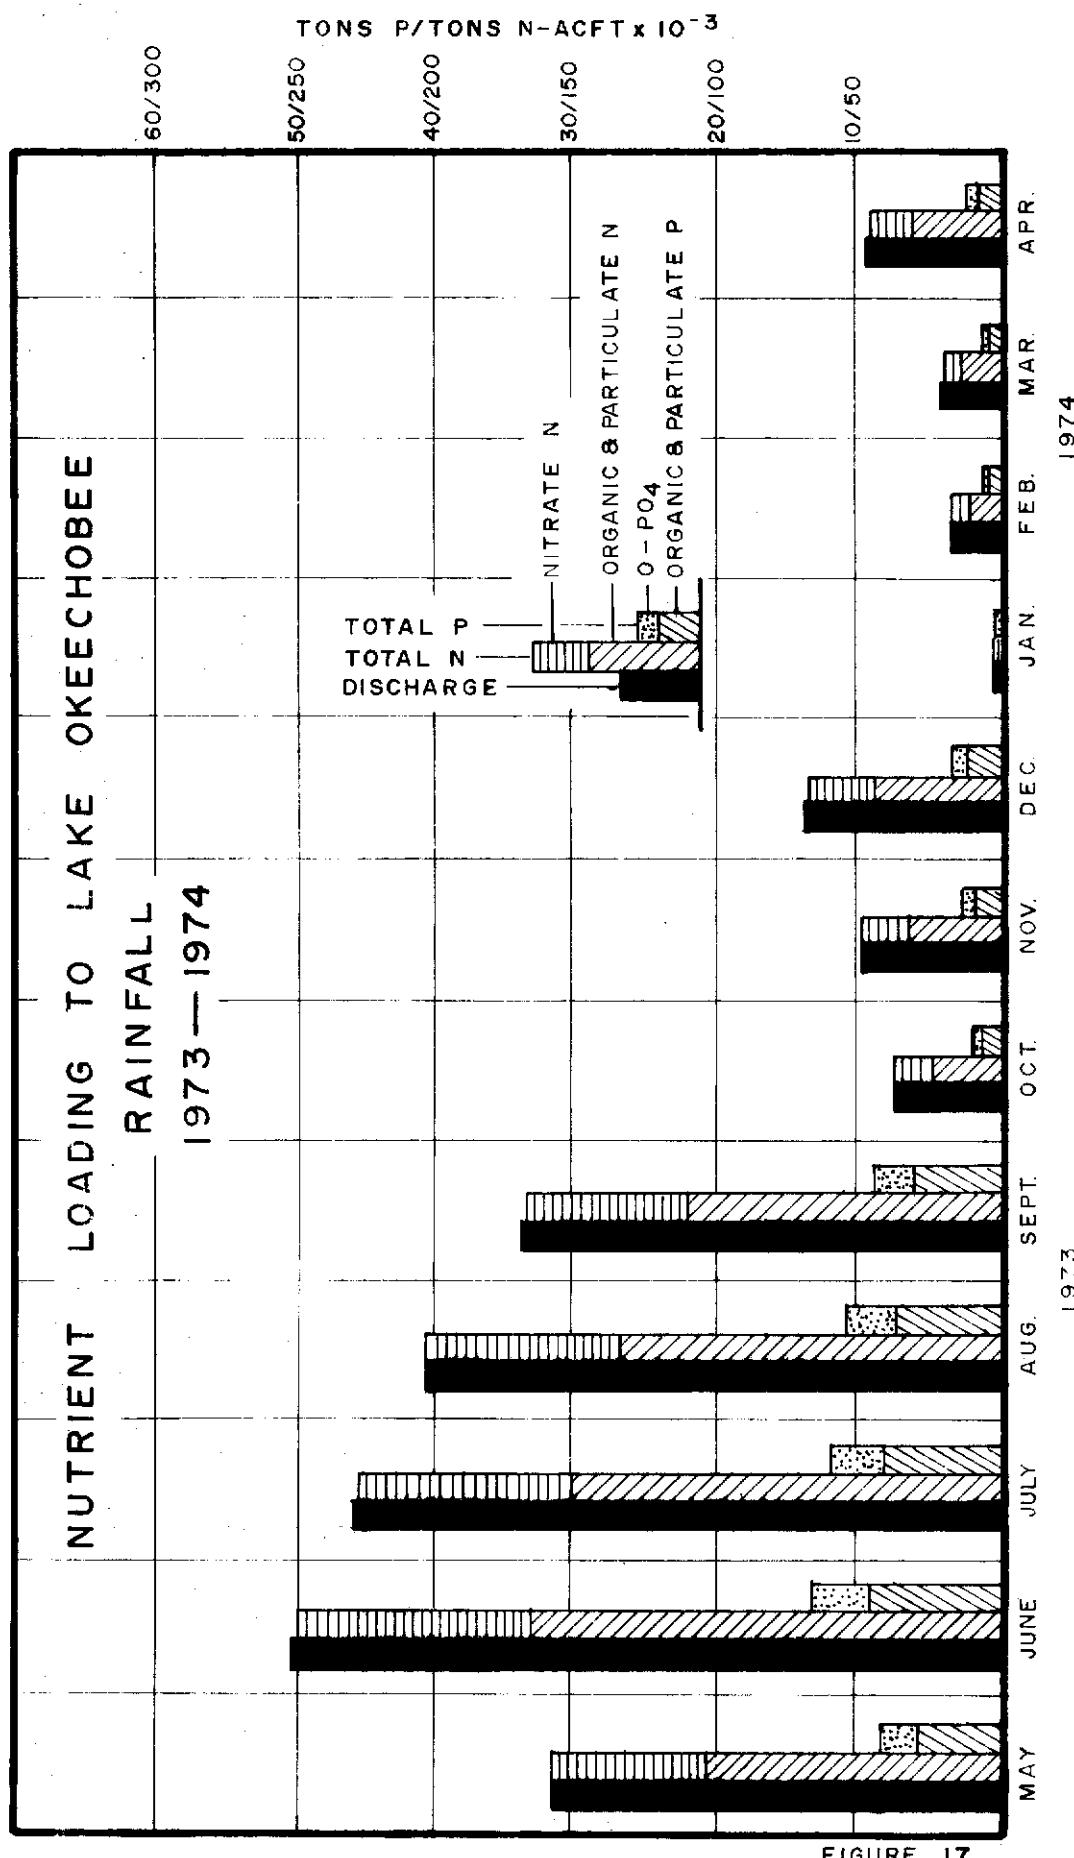

FIGURE 15

to May 1974. The split scales for the Figures have phosphorus tonnage to the left and both nitrogen tonnage and acre-feet of discharge to the right.

The Kissimmee River discharged the majority of its nutrient load to Lake Okeechobee during the period from May to September (Figure 14). The major portion of its nitrogen load was organic or particulate nitrogen with only a small percentage entering the Lake as inorganic nitrogen. The phosphorus load was almost equally divided between ortho-phosphate and particulate or organic phosphorous. As can be seen from the ratio of discharge to element loadings, the concentration of phosphate seems to have peaked in the early part of the high discharge period (July) whereas nitrogen concentrations steadily increased from July to September.

Nubbin Slough was the single largest source of phosphate for Lake Okeechobee during the study period. Figure 15 shows that the majority of this phosphate entered the Lake as inorganic ortho-phosphate. As with the Kissimmee River it also appears that the highest concentration of phosphate occurred during the early part of the peak discharge although the highest discharges occurred earlier in Nubbin Slough than in the Kissimmee River. The relative amounts of phosphorus discharged into the Lake at Nubbin Slough are impressive. In July alone, Nubbin Slough dumped 57 tons of ortho-phosphate into Lake Okeechobee which is enough to more than double the entire Lake's average concentration.

The extremely large quantities of nitrogen supplied to Lake Okeechobee by the agricultural canals occurred predominately during the month of July 1973 (Figure 16). A much larger percentage of inorganic nitrogen was discharged into the Lake by these canals compared to other inflows. The predominate phosphate form was as ortho-phosphate rather than organic and particulate phosphate, as was the case for the Kissimmee River. The 700 tons of nitrate nitrogen discharged

into the Lake by these canals during the month of July is equivalent to over 0.150 mg/l nitrogen for the entire Lake or almost twice the average Lake concentrations.

The rainfall loading data (Figure 17) show no variation in concentrations because yearly average concentrations of nitrogen and phosphorus were used in the calculation. Comparison of rainfall loadings to the previous three loadings does show that rainfall inputs of nutrients are significant over a longer period of time than the surface inflows. Rainfall was responsible for the majority of nutrient inputs to the Lake for the entire dry season from November to May.

Budget Calculations

The water budget for Lake Okeechobee from May 1973 to May 1974 is shown in Table 12. The time period was chosen to include one complete cycle of wet and dry months. The total measured inflow of water during the budget year was 3,008,300 AF. Since the itemized inflow is similar to those used in the loading calculations, the percentage figures for each inflow are the same as shown in Table 11.

The total measured outflow from the Lake was 3,032,500 AF. Of this total 2,152,200 AF or 70% was lost by evaporation. The remaining 30% of the water losses were primarily due to water supply releases to the Glades agricultural area, Caloosahatchee River, St. Lucie Canal and West Palm Beach Canal.

The net volume change calculated from the itemized budget is -24,200 AF or -0.1 foot of stage. The stage record is, however, considerably different. The initial lake stage in May 1973 was 12.40 m.s.l. and the final lake stage in May 1974 was 11.46 m.s.l. This is a net stage differential of -0.96 feet or -346,000 AF net volume differential. The discrepancy between stage records and itemized water budgets is currently under investigation by the FCD but may be

*Rain gauge value reduced 20% based on radar rainfall data (Riebsame et al., 1974)

due simply to the sensitivity of the methods employed in collection of hydrological data.

Material budgets for Lake Okeechobee are shown in Tables 13, 14, and 15, and are, of course, based on the water budget in Table 12. The initial and ending storage values represent the amount of material in solution at the beginning and end of the budget period. Computed storage is the initial storage plus the total inflows minus the total outflows. The "other sinks" represent the difference between computed storage and ending storage.

The budget for the major ions (Figure 13) indicates that more sodium, calcium and chloride entered the Lake during the year than can be accounted for by outflows or ambient Lake concentrations. Approximately 50% of all incoming material must be accounted for in other sinks. The possible other sinks for the comparatively unreactive elements such as sodium and chloride are very limited in natural systems. Calcium may be precipitated out of solution as calcium carbonate, which is a distinct possibility in Lake Okeechobee. However, the large discrepancy in the water budget may be the principle reason for the large and unaccounted for major ion sinks.

The validity of the two nutrient budgets in Tables 14 and 15 are also affected by the poor balance in the water budget. Both the six (Figure 14) and 12 month (Figure 15) budgets show considerable loss of nutrients to other sinks. For nutrients, the possible sinks other than outflow are numerous. For inorganic nutrients, other sinks can imply conversion to particulate and organic forms by primary producers. Additional nutrient sinks include ingestion by primary consumers, losses to littoral zones, sedimentation of detrital material, atmospheric losses (denitrification), and, for phosphate, precipitation and adsorption.

Comparison of the six month budget to the full year budget shows that the majority of the nutrient inputs took place during the wet season, but that most

of these nutrients were apparently removed from the Lake water within six months by means other than outflow. That is, the majority of the incoming nutrients are accounted for in other sinks rather than ending storage.

The losses to other sinks for both organic and total forms of nitrogen and phosphorus for both the six and twelve month budgets are at least 80% of the total inputs. In the case of total phosphates, losses to other sinks were actually greater than inputs, implying a reduction in ambient concentrations. For the budget year, 85% of the total phosphate and 50% of the total nitrogen available to the Lake were retained in other sinks.

Regression Analysis

The results of regression analyses for selected parameter pairs are shown in Table 16. The assumed dependent variable in Table 16 is listed to the left of its corresponding independent variable. The symbol "*" indicates that the slope was significantly different from zero for a 95% one-tailed test; while "**" denotes significance for a 99% one-tailed test. The coefficients of determination for each significant regression are also shown in the table as " r^2 " values.

The nutrient parameters (total phosphate, ortho-phosphate, TKN and nitrate) were assumed to be dependent on several physical and biological parameters including turbidity (Secchi disc readings), wind stress, primary productivity (PPR) and phytoplankton densities (CCT). Wind stress is reported as Effective Displacement Index (EDI). The biological parameters were in turn assumed to be dependent upon physical factors.

Since several relationships were suspected to be reciprocal, the inverse of the physical and biological parameters were correlated with the nutrient data.

Five sets of data were used in the regression procedure. One set included

all data for parameter pairs for all stations. The other sets of data were limited to: 1) winter values only (January 1973 through May 1973); 2) summer values only (June 1973 to October 1973); 3) data from stations with soft sediments (Stations 2, 3, 4, 6 and 8); and 4) data from stations with hard sediments (Stations 1, 5, and 7).

Although the correlation analysis showed that many relationships were statistically significant, the coefficients of determination, r^2 values, indicate that in most cases less than 50% of the variability in the dependent variable can be "explained" by a linear relationship with the independent variable.

Table 16 indicates that the variations in the nutrient parameters were generally dependent on water clarity as measured by Secchi disc readings and occasionally dependent on biological activity as measured by gross primary productivity and/or phytoplankton densities. The statistically significant relationship between nutrient parameters and turbidity is not unusual since turbidity is a function of both inorganic suspended matter and cellular material. Either of these forms of particulate matter could be expected to contain significant quantities of nitrogen and phosphorus and affect the levels of both the particulate and dissolved forms of nutrients. Further analysis of Table 16 indicates that this turbidity (Secchi disc reading) is dependent upon wind stress. This dependency suggests that the turbidity in the Lake is due primarily to resuspension of sediment material rather than phytoplankton concentrations.

The regression analyses did not indicate any strong relationships between biological parameters and either chemical or physical parameters. Primary productivity and phytoplankton densities undoubtedly affect the nutrient concentrations and are effected by physical forces. However, the magnitude of the effects are apparently not sufficient to be statistically significant.

Scatter diagrams of all parameter pairs for which any set of data showed statistically significant relationships are shown in Appendix D.

DISCUSSION

General Chemistry

The results of chemical analyses on samples collected from Lake Okeechobee during the initial 18 month period of this study indicate only minor changes in water quality parameters from previous studies. Table 17 summarizes the yearly mean values of selected parameters from the previous USGS study (Joyner, 1972) and this study for the year 1973. The USGS yearly means are based on data generated by much less frequent sampling (2 to 4 times each year), at different sites, and analyzed using different techniques than those represented in the FCD study. Despite this nonconformity in the data, the table does show only minor variations in nutrient concentrations for the five years. There does not appear to be any trend toward increased ambient nutrient concentrations. The apparent decreases in average concentrations for the dissolved nutrients (nitrate and ortho-phosphate) for 1973 are probably due to the fact that the USGS analyses for these parameters were performed on unfiltered samples.

As mentioned earlier, there is very little Lake Okeechobee data previous to the 1969-1972 USGS study. Odum (1954) reported 3 total phosphate values for the periphery of Lake Okeechobee in 1952. These values were 0.003 mg/l P near Belle Glade, 0.007 mg/l P at Clewiston and 0.030 mg/l P near the mouth of Taylor Creek. Although these values are lower than the values in Table 17, the scarcity of the data prohibits any significant conclusions. In 1940 the USGS sampled Lake Okeechobee and reported nitrate values ranging from 0.04 mg/l N to 0.23 mg/l N (Parker, *et al.*, 1955). These results are in very good agreement with Table 17. Again, however, it would be misleading to place any significance on comparisons of these limited data.

TABLE 17

AVERAGE WATER QUALITY PARAMETERS
 LAKE OKEECHOBEE
 1969 to 1973

Parameter	Year				
	1969 (1)	1970 (1)	1971 (1)	1972 (1)	1973 (2)
Lake stage m.s.l.	14.91	14.55	12.40	13.32	13.34
Ortho-phosphate mg/1 P	0.016	0.054	0.036	0.029	0.005
Total phosphate mg/1 P	0.024	0.070	0.051	0.038	0.071
Nitrate mg/1 N	0.164	0.170	0.181	0.124	0.067
Total Nitrogen mg/1 N	1.38	1.48	1.64	2.21	1.48
Ammonia mg/1 N	0.040	0.039	0.081	0.040	0.026
Sodium mg/l	41.7	31.3	40.0	50.9	55.7
Chloride mg/l	62.9	47.7	60.8	74.3	86.6
Calcium mg/l	44.3	41.1	49.1	55.2	48.0

(1) U.S.G.S. Data (Joyner, 1973)

(2) F.C.D. Data

The record of major ions in the Lake for the five year period as shown in Table 17 may indicate an increase in sodium and chloride levels, but calcium concentrations seem to be fairly stable. Sodium and chloride results from the 1940 USGS sampling in Lake Okeechobee were in the range of less than 20 mg/l for sodium and 30 to 40 mg/l chloride. However, calcium concentrations measured in that study were 35 mg/l to 40 mg/l. Changes in major ion concentrations may be due to increases in the sodium and chloride content of inflowing water or due to the fact that calcium is saturated with respect to carbonates in the Lake.

Most previous studies have questioned the relatively high and apparently increasing total dissolved solids (TDS) in Lake Okeechobee. Since the concentrations of major ions in the inflows do not account for the ambient Lake concentrations, several hypotheses for the high concentrations have been advanced. These include dissolution of the bottom (Parker,et al., 1955), dissolution and groundwater inputs (Joyner, 1972) and concentration due to evaporation and groundwater inputs (Brooks, 1974). The study reported here attempted to approach the TDS problem on the basis of individual ions rather than estimates based on specific conductance. It was hoped that the calculation of individual major ion budgets would identify the reasons and sources for high TDS in the Lake. Unfortunately the poor results of the budgets prevent further analysis of the data. The magnitude of excess major ions as calculated from the budget is virtually impossible to explain.

The apparent increases in sodium and chloride but not calcium over the last 30 years indicate that groundwater seepage or concentration due to evaporation would be the most reasonable causes for high TDS in the Lake. Dissolution of bottom sediments would most likely cause increases in calcium rather than sodium and chloride . Concentration effects from evaporation would tend to increase all

ions equally unless there were precipitation effects concurrent with the evaporation. The high pH alkalinity in Lake Okeechobee may cause calcium to precipitate as calcium carbonate although there is no direct evidence for precipitation.

The results of monthly sampling at eight locations within Lake Okeechobee indicated significant seasonal and areal variations in water chemistry. The major ions generally reflected the effects of inputs of low TDS by major inflows. However, linear regression of Lake stage and rainfall with major ion concentration did not indicate a statistically significant relationship. The possible inputs of highly mineralized groundwater may have had significant effects on major ion concentrations.

Nutrient parameters showed much greater variation, both seasonally and areally, than did major ions. The variations are somewhat more complex since many factors can be involved. Although the yearly means of nutrient parameters at each sample station showed that stations near major inflows were apparently affected by high discharges of nutrients, the monthly and seasonal means of these parameters indicated that several months lapsed between the time of peak discharge and the time when elevated nutrient concentrations were measured in the Lake. It is possible that the station locations were too far from points of inflow to show the nutrient input effects before biological uptake or other mechanisms reduced the effects.

Both nutrient levels and biological activity as measured by primary productivity and phytoplankton density, appeared to show the same seasonal patterns of spring and fall maximums, and summer minimums, but statistical analyses did not indicate any significant relationships between them.

Loadings and Budgets

The loadings of nitrogen and phosphorus material to Lake Okeechobee during the year May 1973 to May 1974 were less than those reported by Joyner (1972) for the year 1969-70. The USGS study showed 2,000 more tons of nitrogen and 200 more tons of phosphorus entering the Lake. However, the volume of water entering the Lake during 1969-70 (6,361,000 AF) was far greater than during 1973-74 (3,008,000 AF), which accounts for the higher loadings. The majority of the discharge loading increases were due to the Kissimmee River while the remaining inflows showed comparable values for both discharge and loadings during both studies.

Comparison of discharge water quality (Table 11) and land use indicates two basic relationships. Water quality in the agricultural canals which drain crop lands is characterized by high nitrate values. In contrast, the runoff water from areas devoted primarily to pasture has high phosphorus concentrations. Since little nitrogen fertilizer is used in the Miami, Hillsboro and North New River Canal basins the high nitrate values in these canals are probably due to leaching of nitrate from the organic soils. Neller (1944) reported rapid nitrification in Everglades peat and suspected that these nitrates would be leached out of the soil by rainfall. The high phosphate in Nubbin Slough, Harney Pond Canal and Indian River Canal may be due to animal waste, which would be particularly concentrated in the Nubbin Slough basin due to heavy dairy activity. The second possible source of the phosphorus is the natural phosphate deposits in these basins. Odum (1955) shows some natural phosphate

deposits in the Nubbin Slough drainage basin and indicated that elevated phosphate levels in natural waters may be due to leaching of such deposits.

The imbalance of the water budget used in this study limits the significance of the materials budgets. The high loss rate of nutrients is, however, in agreement with evidence for biological response to the high nutrient loadings. Also, the elemental ratio of nitrogen to phosphorus lost to other sinks was 20:1, which compares favorably to the average elemental ratio of 16:1 (nitrogen: phosphorus) in cellular material. Thus, although the absolute amount of nutrients retained by the Lake according to the budgets may be in error, the relative amounts lost to other sinks suggest that they were fixed into cellular material.

Regression Analysis

The classical patterns of decreasing inorganic nutrients with increasing phytoplankton densities, productivity, or total nutrients were not evident from the chemistry data. Occasional instances of inverse relationships between inorganic nutrients and biological parameters were indicated by the regression analyses data, but no consistent pattern developed.

Linear regression did suggest that nutrient parameters were dependent upon Secchi disc readings which were in turn dependent upon wind stress as measured by EDI. The relationships showed that as wind stress increased Secchi disc readings decreased and nutrient parameters increased. These relationships may mean that wind stress was creating enough wave action to suspend sediment material and subsequently release previously bound inorganic nutrients. The resuspension of bottom material would in itself tend to increase the total nutrient levels. The budget calculations of both this study and the previous USGS study (Joyner, 1972) indicated that considerable amounts of nitrogen and phosphorus may be retained in the Lake as sediment material. The results of

Ekman sampling indicate that unconsolidated sediments (primarily a fine black mud) are found generally in the central and northeastern portions of the Lake. Linear regression analyses of nutrient parameters at mud bottom stations with Secchi disc readings and EDI indicated a strong dependency of nutrients on the wind stress.

Joyner (1972) estimated that the average wind speed on Lake Okeechobee was 9 mph and that this wind speed would effectively mix the water column to a depth of 8.4 feet (2.6 m). The EDI for a 9 mph wind blowing constantly for 5 days would be 0.35 g/cm/sec^2 . Measured EDI's for this study were never above 0.35 g/cm/sec^2 but mean surface and bottom chemistry values indicated that the Lake was well-mixed. The large fetch and shallow depth of Lake Okeechobee apparently produced effective mixing and possible resuspension of bottom sediments with even relatively minor wind stresses. Although there are only limited data on both the physical and chemical characteristics of sediments in Lake Okeechobee, the results of this study indicate that physical forces acting on the sediments may be instrumental in determining the areal and seasonal distribution of major nutrients within the Lake and ultimately the biota of the Lake.

Primary Productivity

Based on data collected for other Florida lakes by Brezonik, *et al.* (1969), Lake Okeechobee primary productivity values were high, $1864 \text{ mg C/m}^3/\text{day}$ or $161 \text{ mg C/m}^3/\text{hour}$. A listing of the gross primary productivities for Lake Okeechobee and various Florida lakes is presented in Appendix E.

Factors which affect primary productivity include physical parameters such as temperature, light intensity, water transparency, and turbulence, and chemical parameters such as major and minor nutrients, pH, and alkalinity.

These factors undoubtedly help to determine the composition and condition of the lacustrine biota.

Although consistent relationships among primary productivity, nutrient, and physical parameters were not observed (Table 16), certain trends were indicated. Aside from biological considerations, physical-water clarity (Secchi disc readings) and EDI (wind stress)--rather than nutrients--total phosphate, ortho-phosphate, total Kjeldahl nitrogen and nitrate--parameters were more often related to primary productivity.

Green algae, especially the small, flagellated, unicellular types, appeared to be responsible for much of the primary productivity in Lake Okeechobee. Primary productivity at Station 4 in the spring (Figure 10) was higher when the phytoplankton population was dominated by these green algae (Figure 13) than when it was dominated by blue-green algae. This trend was observed at other productivity stations but was much less conspicuous.

Phytoplankton Populations

Information on the phytoplankton of Lake Okeechobee, and subtropical lakes in general, is very limited. The USGS report by Joyner (1972) is the only known source of information on Lake Okeechobee phytoplankton. The phytoplankton observed in this study differ significantly from those reported by the USGS. None of the dominant phytoplankton observed by the USGS were dominant during the FCD study. The USGS report listed 24 species of phytoplankton common to Lake Okeechobee. To date, the FCD study has revealed 83 species. The USGS did not report the presence of any euglenoids or small

green flagellates. The FCD study indicated that the small green flagellates dominated the green algae. Although a time lag exists between USGS data and the data from this study, a drastic change in phytoplankton probably did not occur. Differences in sampling technique, sampling frequency, counting procedures, and taxonomic references may account for the differences.

The algal populations of several other Florida lakes have recently been studied. Lake Tohopekaliga was studied from June 1970 to January 1972 (Holcomb and Wegener, 1972). The species list for this lake was quite similar to the list compiled by the FCD for Lake Okeechobee. However, the dense blooms of Aphanizomenon and Anabaena characteristic of Lake Tohopekaliga were not found in Lake Okeechobee.

In 1966 and 1967, Lackey (1967) found that Lakes Apopka, Dora, Carlton, Beauclaire, and Griffin were dominated by blue-greens. These lakes contained the same algae which were present in Lake Okeechobee. Persistent blue-green blooms were observed in Lakes Apopka and Dora throughout the year. Although blue-green algae dominated the phytoplankton of Lake Okeechobee, the blooms did not persist and blue-green algae did not dominate to the exclusion of all other algae.

The dominance of a lake by blue-green algae may be closely related to water chemistry. Several authors have observed the dominance of blue-green algae in alkaline conditions and their relative absence in acid conditions (King, 1970; Shapiro, 1973; Fogg, 1956; Prescott, 1970; Brock, 1973; Brezonik, et al., 1969).

The relationship between pH and algal population was observed in several other Florida lakes (Marshall, 1974, unpublished data). Lakes Tohopekaliga and Kissimmee with a pH range of 8.1 - 8.8 were dominated by blue-green algae. Lakes Cypress and Hatchineha with pH values ranging from 6.2 - 7.2 were dominated by green algae and diatoms, respectively. East Lake Tohopekaliga had a pH range of 6.7 - 7.1 and was dominated by diatoms and dinoflagellates.

Alkaline pH in Lake Okeechobee, 8.2 to 8.4, may be a contributing factor to the dominance by blue-green algae.

Blue-green algae often give the impression of being favored by warm and nutrient-rich conditions (Fogg, et al., 1973). However, Pearsall (1932) and Hutchinson (1967) observed that blue-green algae tended to grow most rapidly when concentrations of inorganic nutrients such as nitrate and phosphate were lowest. The abundance of blue-green algae during periods when nutrients are reduced may be explained by the adaptive physiology of these organisms. Blue-green algae are able to store large quantities of nitrogen (Stewart, 1972) and phosphorus (Stewart and Alexander, 1971) and utilize them during periods of nutrient deprivation. It is paradoxical that although they tend to develop at times of nutrient deficiency, planktonic blue-green algae are nevertheless characteristic of waters receiving high nutrient inputs (Fogg, et al., 1973). Vollenweider (1968) from surveying the available literature, concluded that massive growth of blue-green algae is likely if nutrient concentrations exceed 0.01 mg/l P and 0.2 - 0.3 mg/l N in the spring and/or if the loading per unit area per year of the lake reaches 0.2 - 0.5 mg/l P and 5 - 10 mg/l N. The average nutrient concentration and loading rates of phosphorus for Lake Okeechobee found in this study are within the above ranges quoted by Vollenweider.

Blue-green algae blooms have been shown to be triggered by phosphate (Schindler, 1974). Examination of phytoplankton and loading data for Lake Okeechobee tends to support this observation. The large influx of ortho-phosphate in July, particularly from Nubbin Slough (Figure 15), may have triggered the pulse of blue-green algae observed during that month at Station 1 (Figure 13). Similarly, at Station 5 loadings of ortho-phosphate from Fisheating Creek reached a maximum sometime between the middle of August and middle of October, as did peaks in blue-green algae populations (Figure 13).

Fall increases in blue-green algae concentrations were not as great as Stations 4 and 6, as they were at Stations 1 and 5 (Figure 13). This may indicate that most of the fall ortho-phosphate loading was removed at the peripheral stations (1 and 5) and did not reach the more distant stations (4 and 6).

The increase in blue-green algae concentrations during the spring pulse was greater at the centrally located stations (4 and 6) than at the peripheral stations (1 and 5). Stations 4 and 6 had mud bottoms whereas Stations 1 and 5 had sand bottoms. The greater response of blue-green algae (increases in densities at Stations 4 and 6 may be explained by a release of ortho-phosphate from the mud bottoms.

The abundance of green algae in Lake Okeechobee, especially the small, flagellated, unicellular types appear to be related to nitrate loadings. Large amounts of nitrate were pumped into the Lake by S-2 and S-3 during July (Figure 16). The high loading of nitrates and relatively low loading of ortho-phosphate may account for the comparatively high percentages of green algae and low percentages of blue-green algae at Stations 6 and 7 (Figure 11). In contrast, the low ambient nitrate concentrations may account for the low percentages of green algae at Stations 1 and 5.

Trophic State

There are many methods of estimating the trophic level of lakes and several systems of classifying such levels. The chemical and biological data collected during the initial 18 months of this study are adaptable to several of these methods. It should be noted that Lake Okeechobee lies within the semi-tropical climatic zone and that many of the principles defining trophic state classification were developed from data collected on temperate zone lakes. A summary of several trophic state classification systems and Lake Okeechobee trophic level according to each system is presented below:

<u>Reference</u>	<u>Classification Base</u>	<u>Lake Okeechobee Trophic Level</u>
Brezonik, <u>et al.</u> (1969)	Primary Productivity	Eutrophic
Sakamoto (1966) and Vollenwieder (1968)	Total Phosphate/Nitrate Nitrogen	Eutrophic/Oligotrophic
Vollenwieder (1968) and Shannon & Brezonik (1972)	Loading rates - depth relationship	Mesotrophic

Primary productivity is probably the best trophic state indicator since it is a result of the many factors effecting the rate and level of eutrophication. Comparison of the primary productivity of Lake Okeechobee ($161 \text{ mg C/m}^3/\text{hr}$) to those of other Florida lakes studied by Brezonik, et al. (1969) indicates that Lake Okeechobee would be classified as eutrophic.

One of the simplest methods of determining a lake's trophic level is based on ambient nutrient concentrations within the lake at the winter overturn. Ranges of total phosphate and inorganic nitrogen for the classical trophic types have been compiled by Sakamoto (1966) and Vollenweider (1968). Since Lake Okeechobee has no winter overturn, the yearly average total phosphate, 0.071 mg/l P , and nitrate nitrogen, 0.067 mg/l N , for the Lake were compared to the trophic level ranges of these parameters. The total average phosphate for the Lake falls into the range category of eutrophic lakes ($0.30\text{-}0.10 \text{ mg/l P}$)

according to both systems referenced above. For inorganic nitrogens of less than 0.1 mg/l N both classification systems would consider Lake Okeechobee as oligotrophic. If the maximum monthly means of each parameter are compared to the ranges for each trophic state, there would be no change in the Lake's classification according to these systems.

A second classification system suggested by Vollenweider (1968) is based on the relationship between nitrogen and phosphorus loading rates and mean depths. Shannon and Brezonik (1972) have adjusted these loading rate/lake depth relationships for semitropical lakes based on their analysis of 55 northern Florida lakes. The loading rates of nitrogen and phosphorus to Lake Okeechobee as calculated from the 1973-1974 data were $3.4 \text{ g/m}^2/\text{yr}$ and $0.33 \text{ g/m}^2/\text{yr}$, respectively. These rates applied to a lake with a mean depth of 3 meters place Lake Okeechobee within the mesotrophic level according to Shannon and Brezonik's adjusted relationships and in the eutrophic level according to Vollenweider's relationships.

CONCLUSIONS

The conclusions concerning the chemical and biological characteristics of Lake Okeechobee are summarized below. The conclusions are based on the initial 18 months of an on-going study and may be subject to revision based on additional data.

1. Yearly averages of major nutrients for the period 1969 to 1973 show no significant change.
2. Nutrient parameters (nitrogen and phosphorus) showed seasonal variation with maximum concentrations during the spring and fall and minimum concentrations during the summer.
3. Morphological characteristics of Lake Okeechobee (large surface area and shallow depth), combined with sediment characteristics were critical to the levels and distribution of major nutrients within the Lake.
4. The high nutrient loadings to Lake Okeechobee by major inflows had little direct effect on the ambient water chemistry but may have stimulated biological activity causing rapid uptake of these nutrients.
5. Phytoplankton and primary productivity showed seasonal variations with similar patterns to nutrients i.e. maximum spring and fall values and minimum summer values.
6. Areal variation in primary productivity and phytoplankton populations was probably related to nutrient loadings.
7. Blue-green algae (Cyanophyta) dominated the phytoplankton and appeared to be related to ortho-phosphate. Green algae (Chlorophyta) were less abundant than blue-green algae and appeared to be related to nitrate nitrogen. Green algae also appeared to be responsible for much of the primary productivity in the Lake.

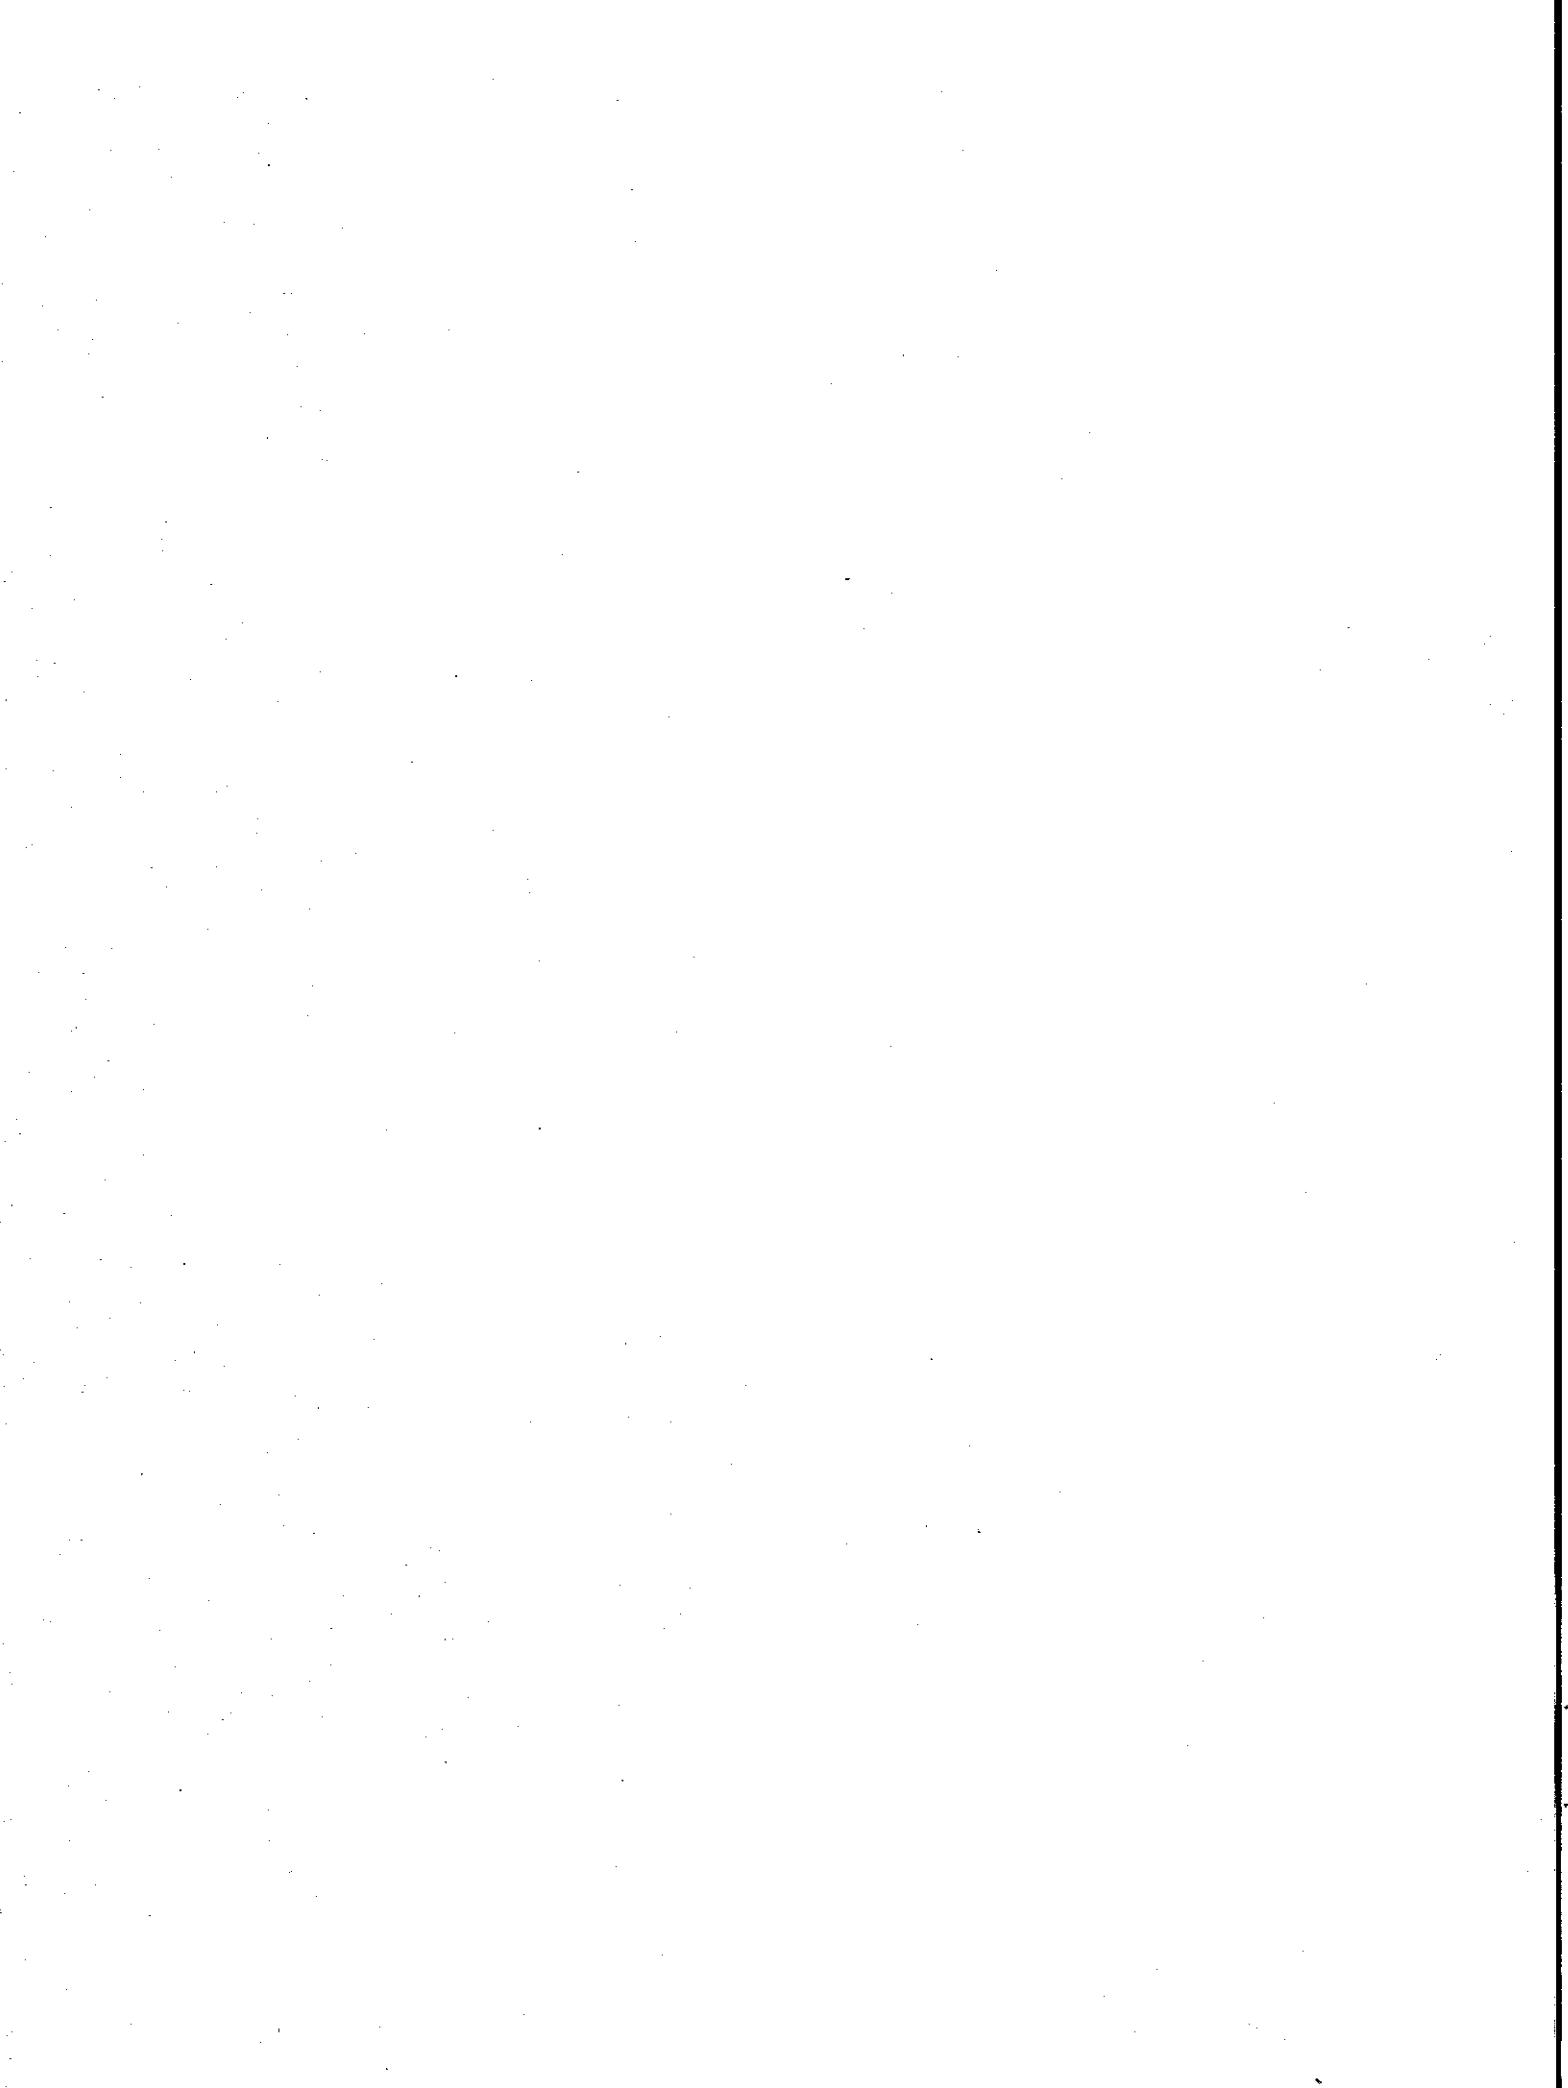

8. Chemical and biological characteristics of Lake Okeechobee indicate that it is in the early eutrophic state but the rate of eutrophication is unknown.

APPENDIX C

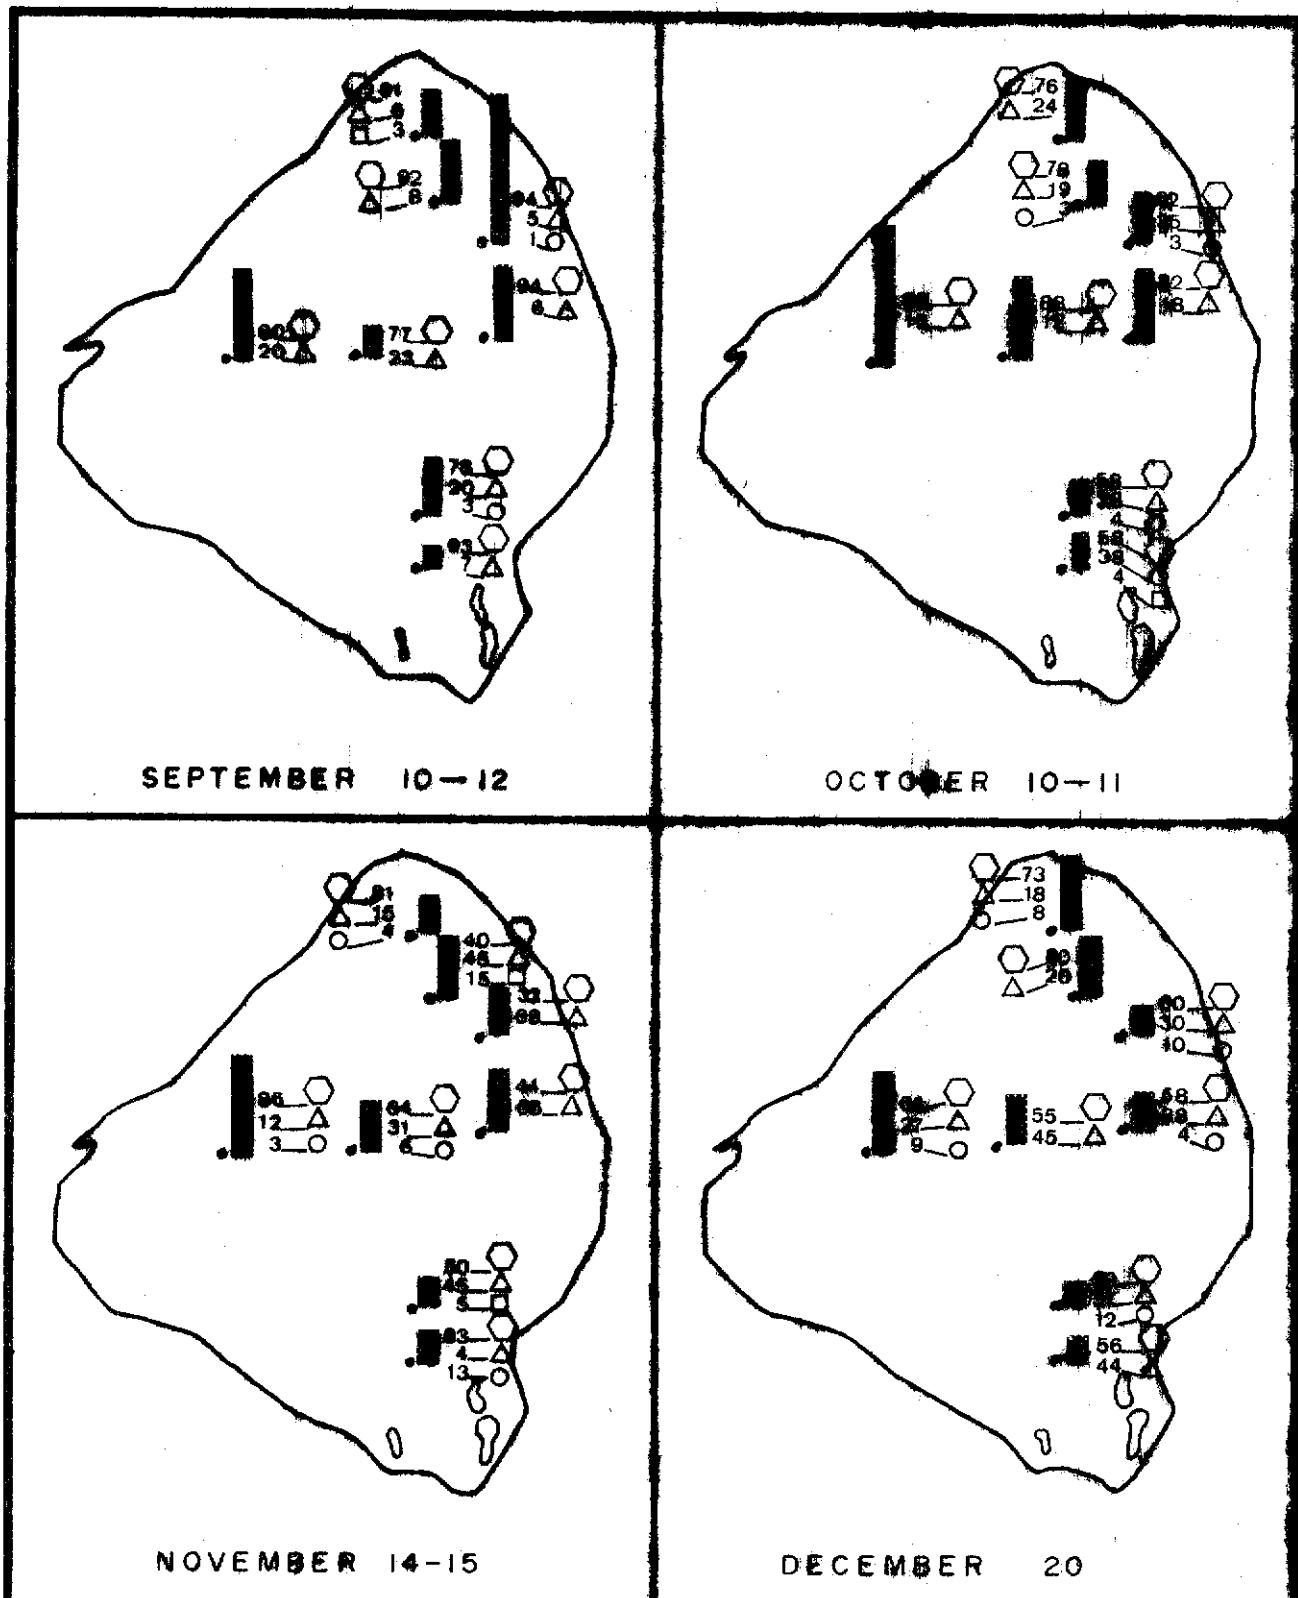

DISTRIBUTION OF PHYTOPLANKTON ABUNDANCES AND COMPOSITIONS

LAKE OKEECHOBEE - 1973

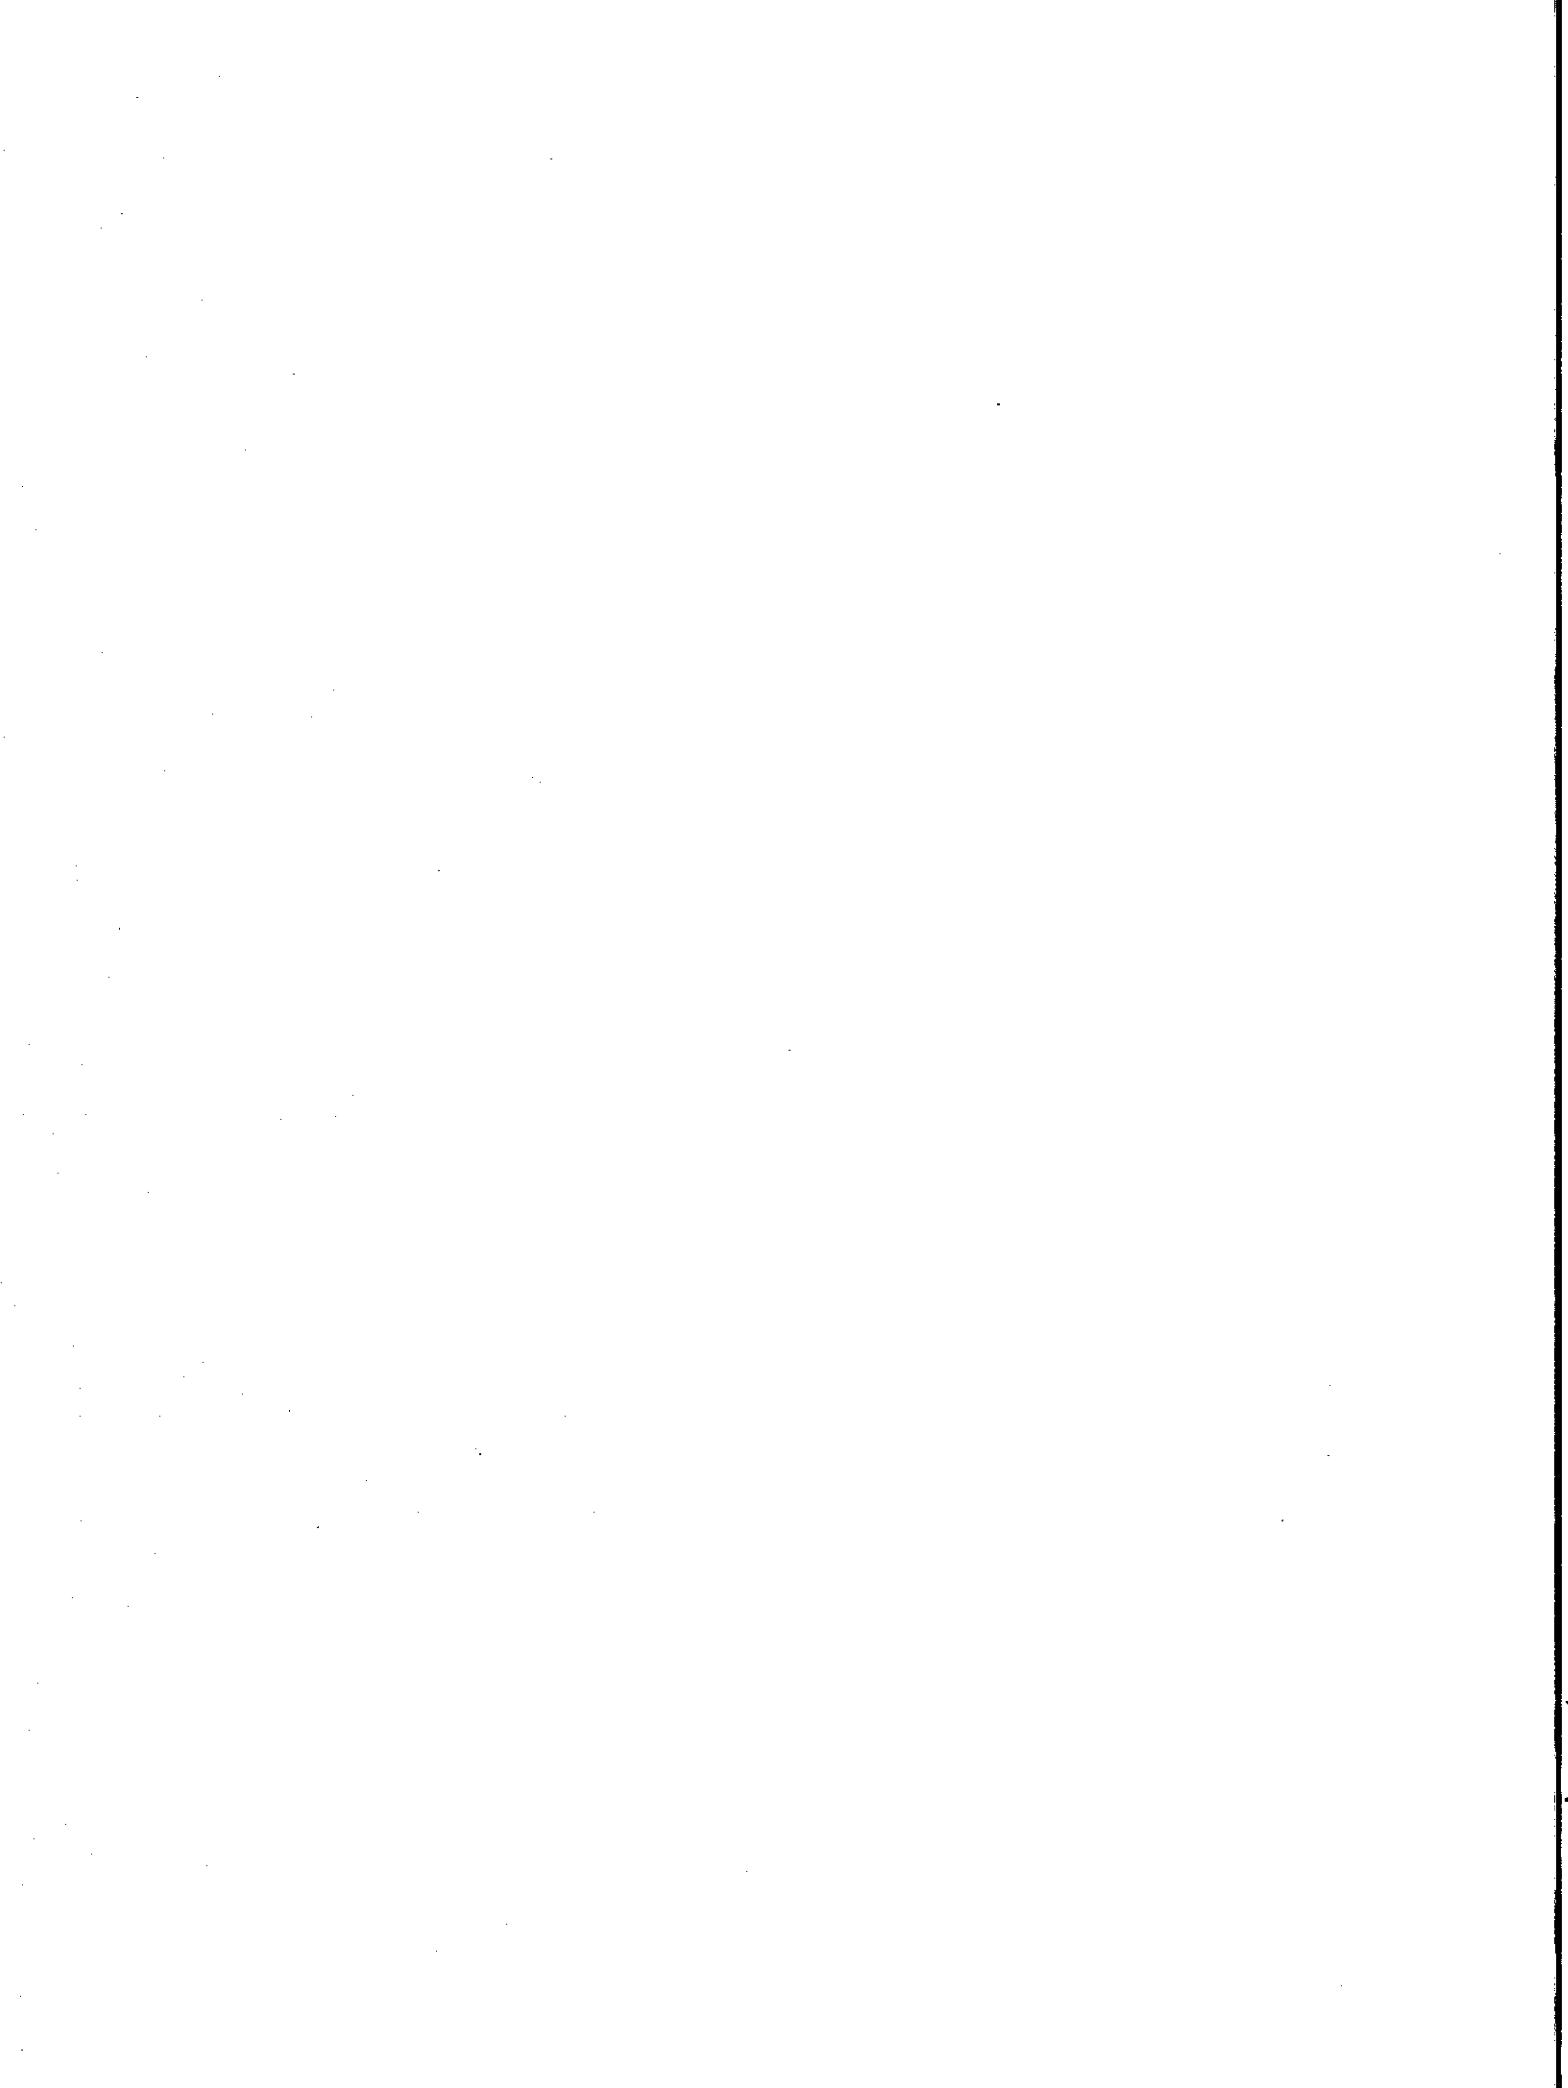

LAKE OKEECHOBEE, 1973
DISTRIBUTION - PHYTOPLANKTON
ABUNDANCE & COMPOSITION

* DATA MISSING

ABUNDANCE	PERCENTAGE
24	Cyanophyta ○
20	Chlorophyta ▲
16	Chrysophyta ◇
12	Euglenophyta □
8	
4	
0	

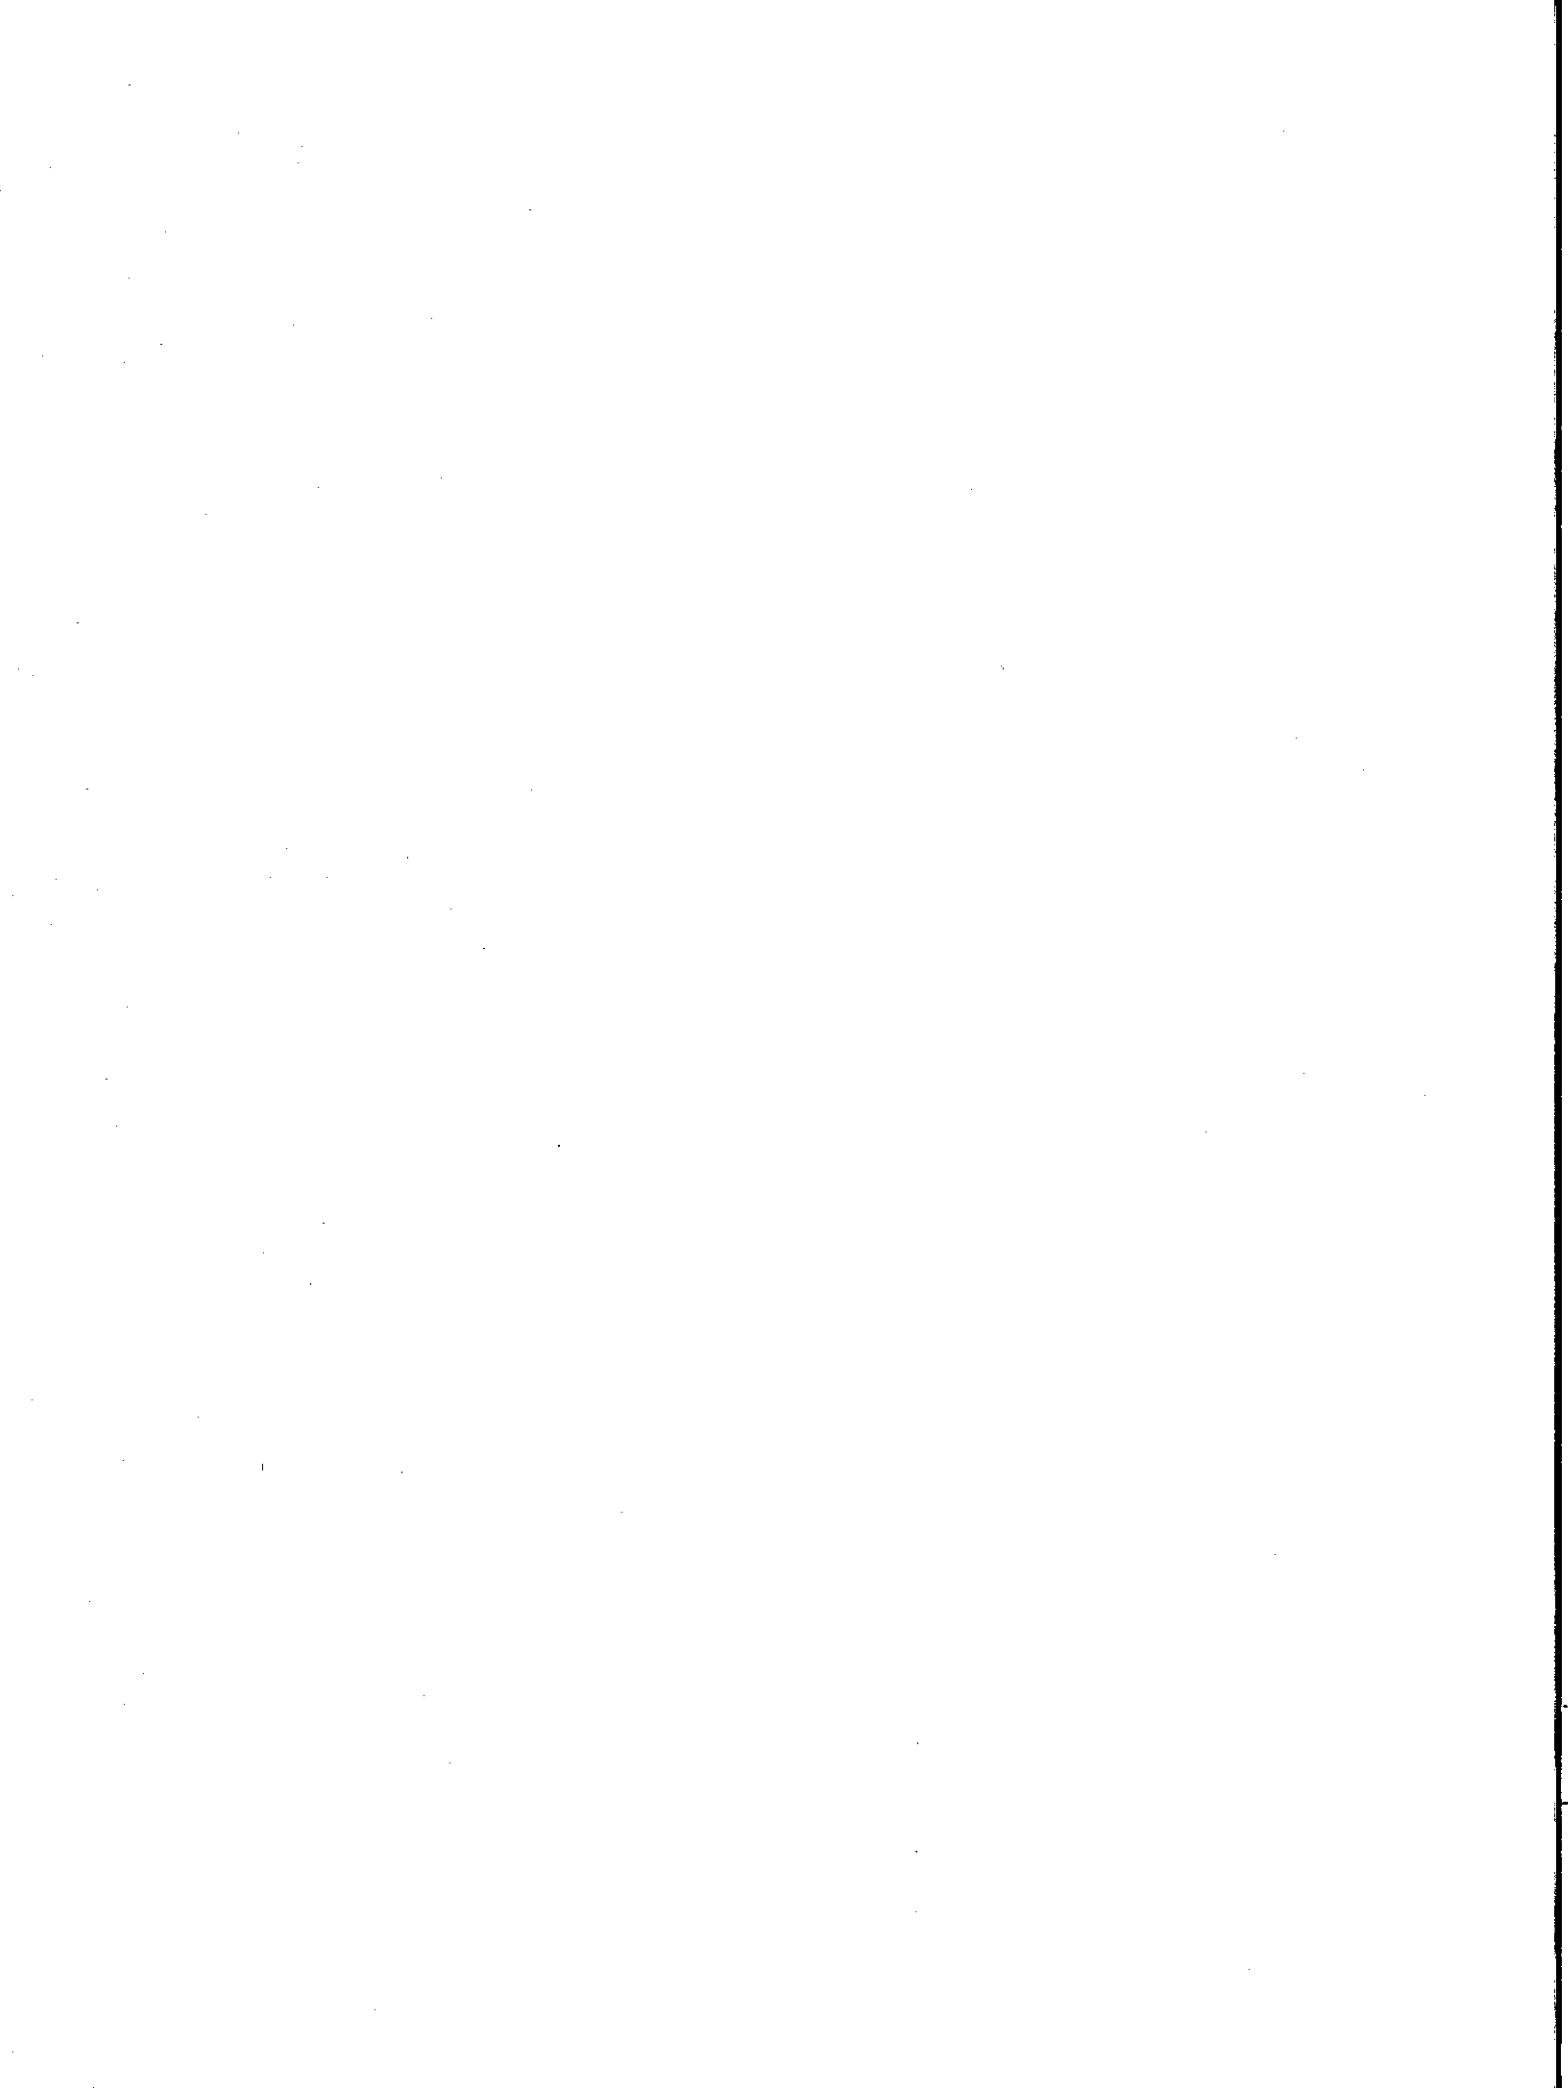

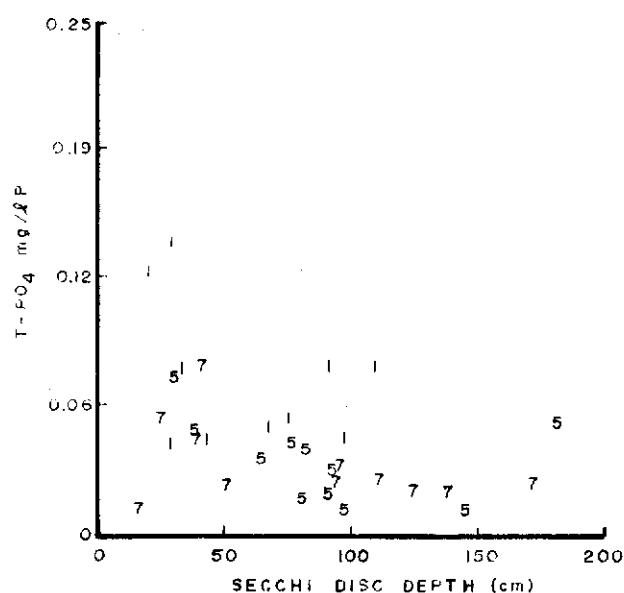

APPENDIX D

SCATTER DIAGRAMS FOR SIGNIFICANT PARAMETER PAIRS

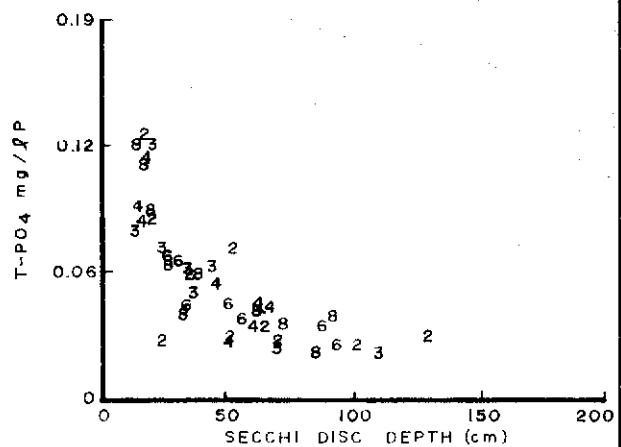

LAKE OKEECHOBEE 1973

Number for data points correspond to sample station numbers.

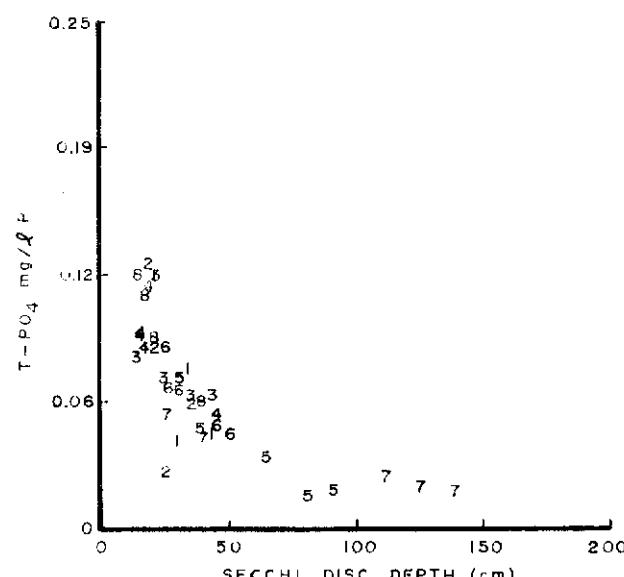

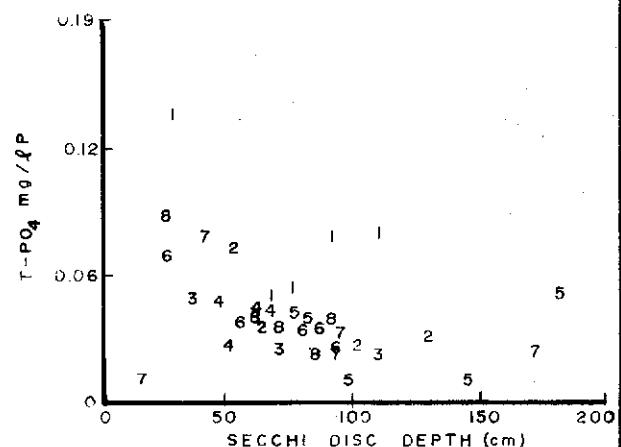

LAKE STATIONS
WITH HARD BOTTOMS

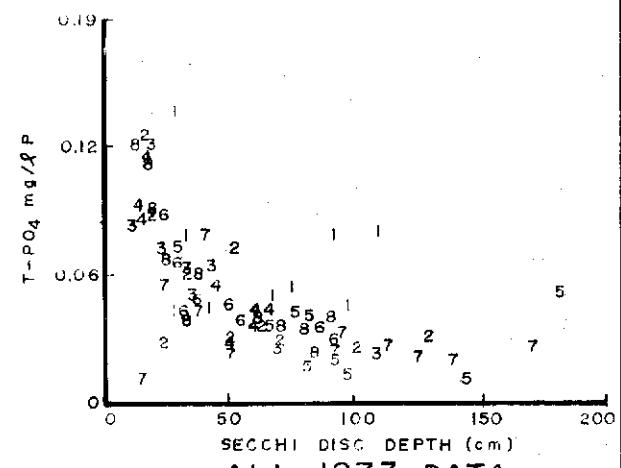

LAKE STATIONS
WITH SOFT BOTTOMS

WINTER (JAN.-MAY) DATA

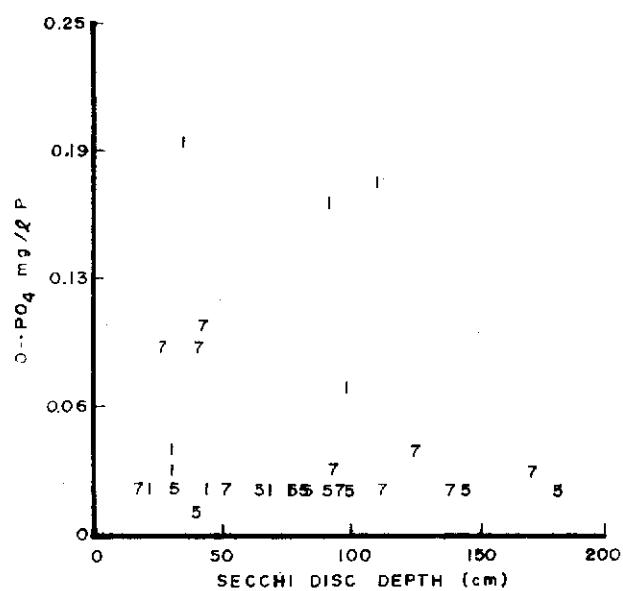

SUMMER (JUNE-OCT.) DATA

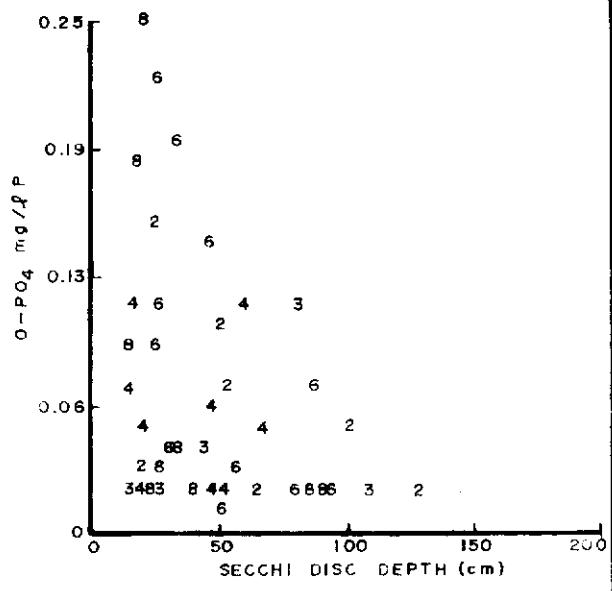

ALL 1973 DATA

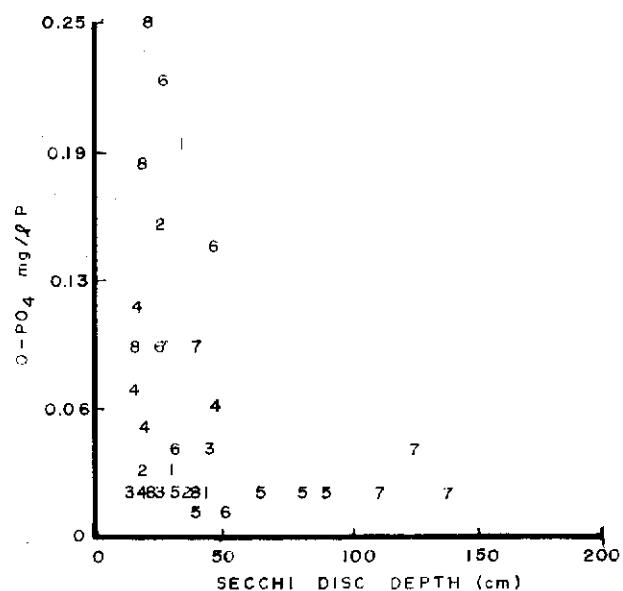

LAKE OKEECHOBEE 1973
TOTAL PHOSPHATE vs SECCHI DISC DEPTH

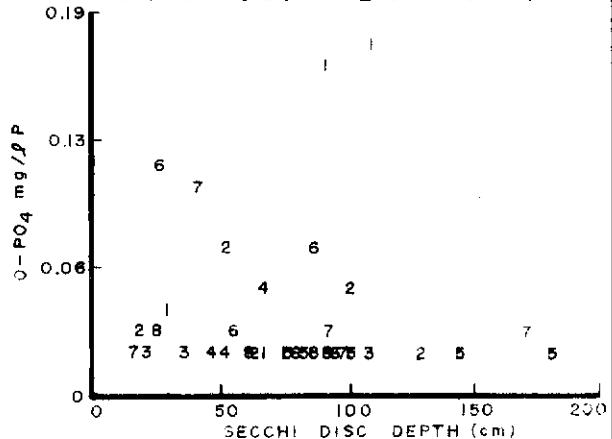

Lake stations with hard bottoms

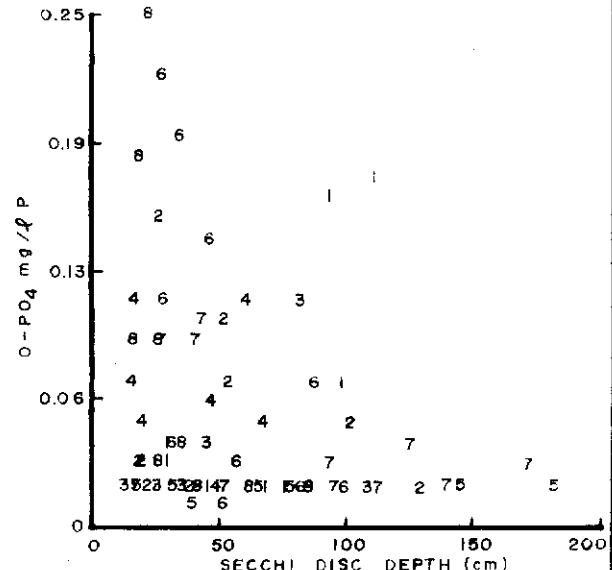

LAKE STATIONS WITH SOFT BOTTOMS

WINTER (JAN.-MAY) DATA

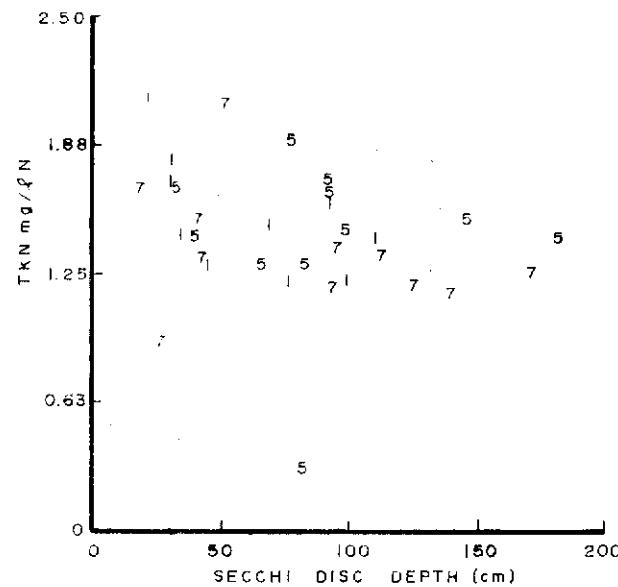

SUMMER (JUNE-OCT.) DATA

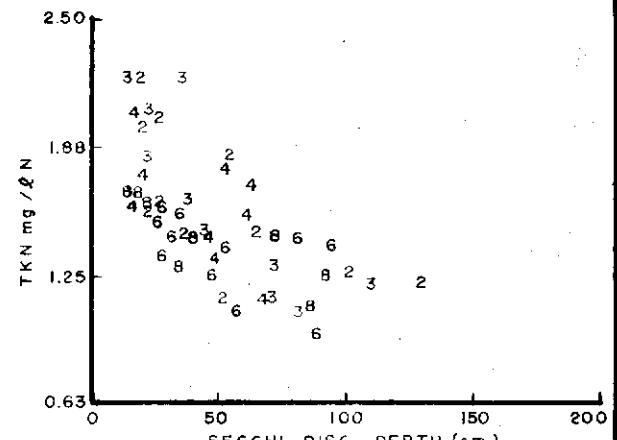

ALL 1973 DATA

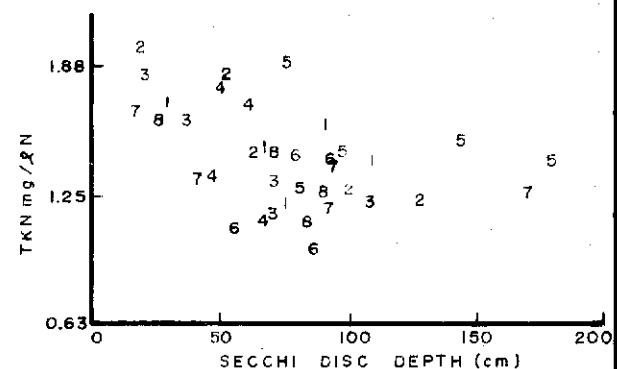

LAKE OKEECHOBEE 1973
ORTHO-PHOSPHATE vs SECCHI DISC DEPTH

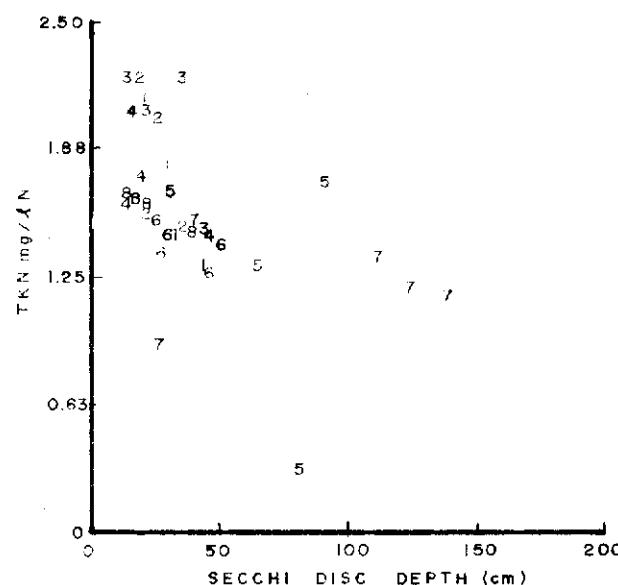

Lake stations with hard bottoms

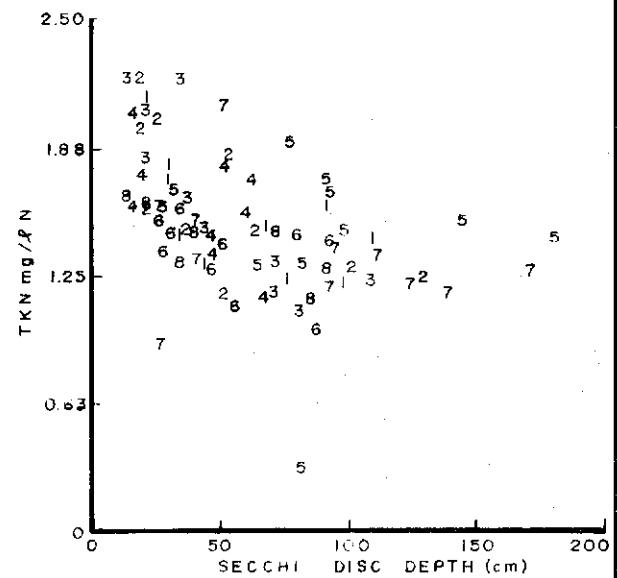

LAKE STATIONS WITH SOFT BOTTOMS

SUMMER (JUNE-OCT.) DATA

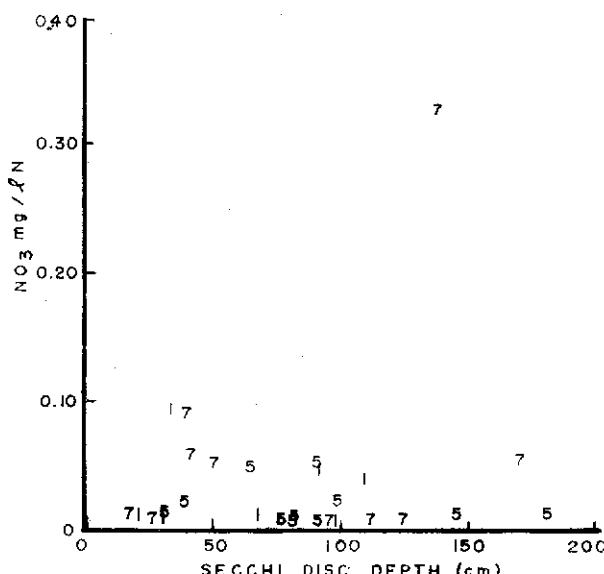

WINTER (JAN.-MAY) DATA

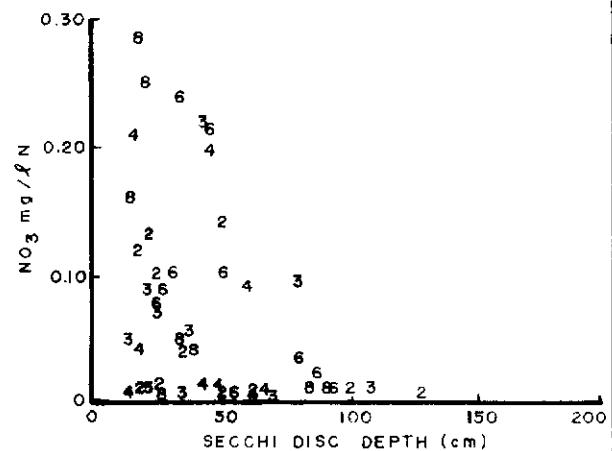

ALL 1973 DATA

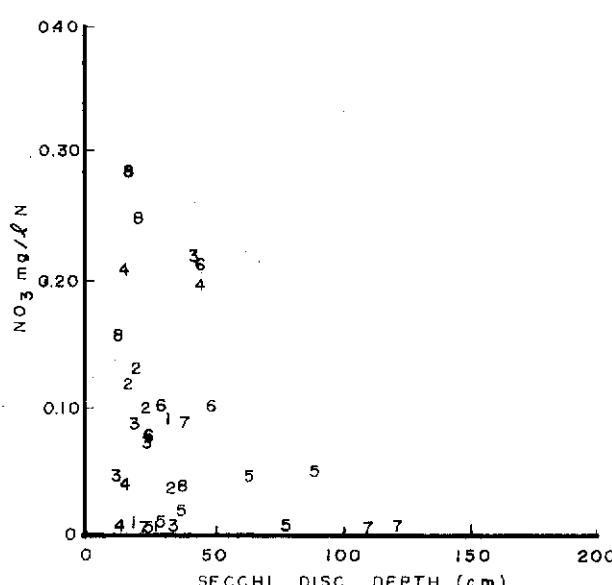

LAKE OKEECHOBEE 1973
TOTAL KJELDAHL NITROGEN vs SECCHI DISC DEPTH

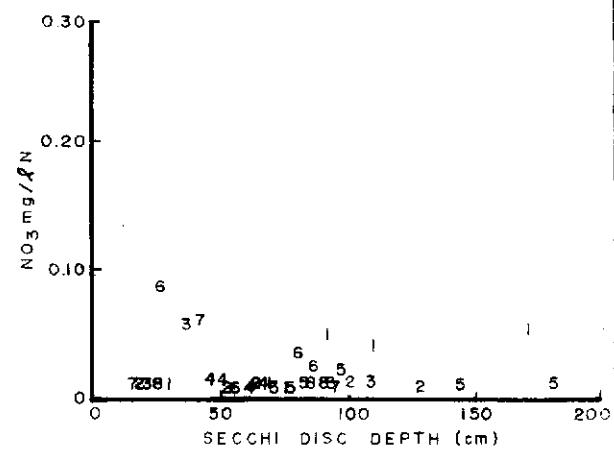

Lake stations with hard bottoms

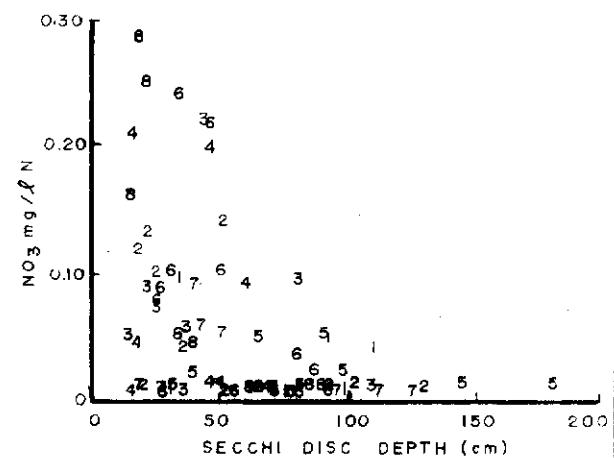

LAKE STATIONS WITH SOFT BOTTOMS

WINTER (JAN.– MAY) DATA

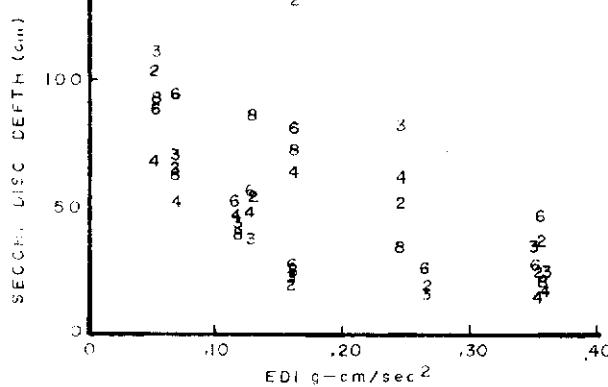

SUMMER (JUNE-OCT.) DATA

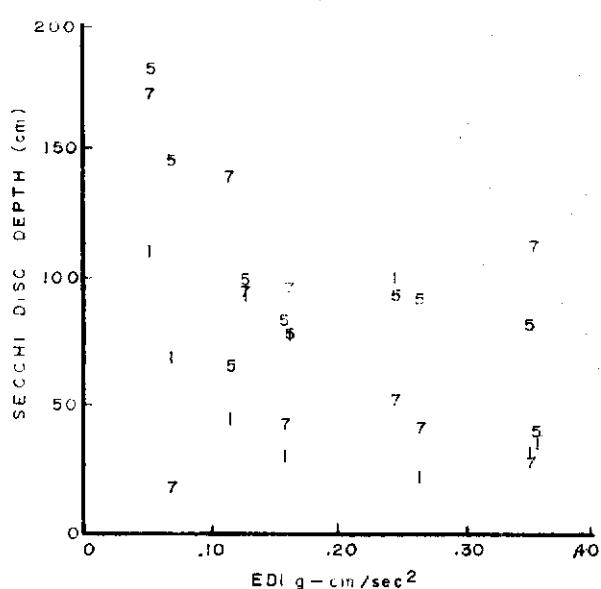

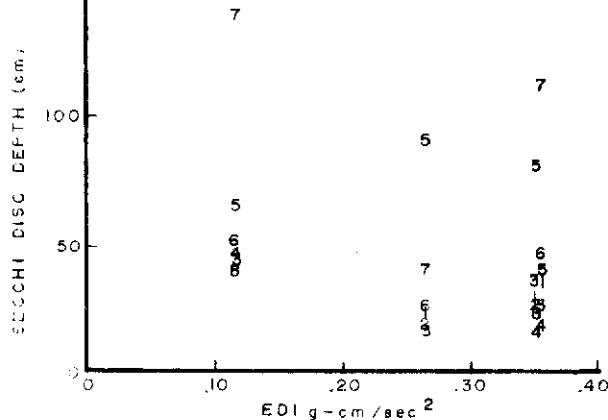

ALL 1973 DATA

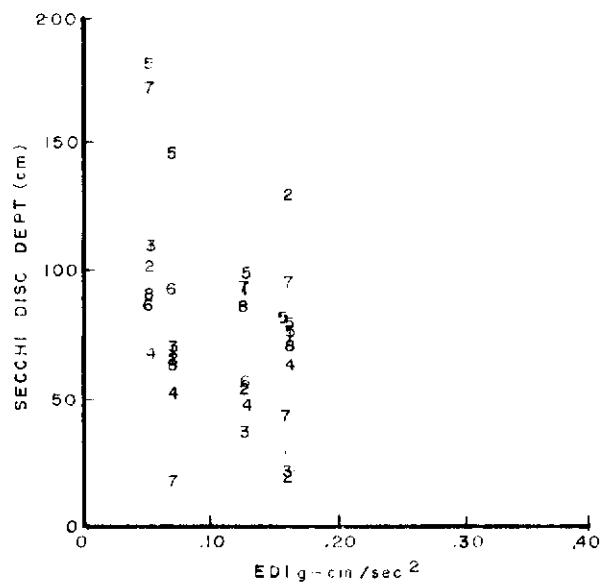

LAKE OKEECHOBEE 1973
NITRATE vs SECCHI DISC DEPTH

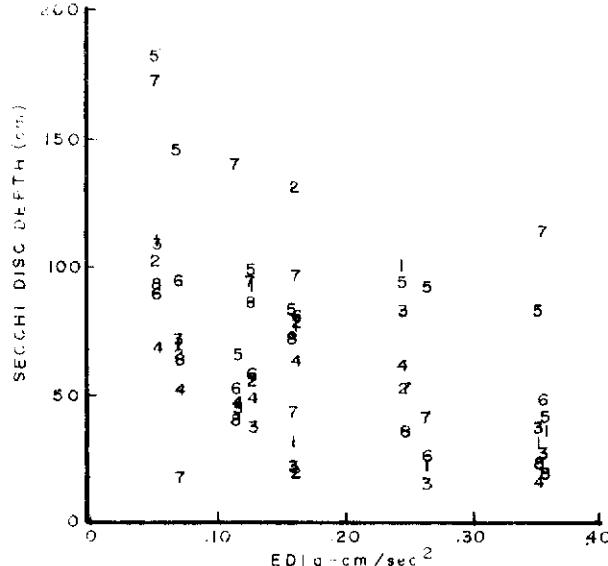

LAKE STATIONS WITH HARD BOTTOMS

LAKE STATIONS
WITH SOFT BOTTOMS

WINTER (JAN-MAY) DATA

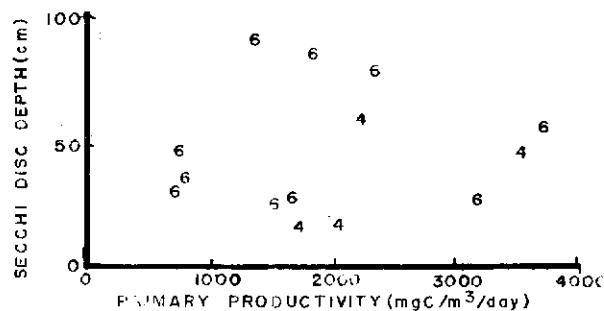

SUMMER (JUNE-OCT) DATA

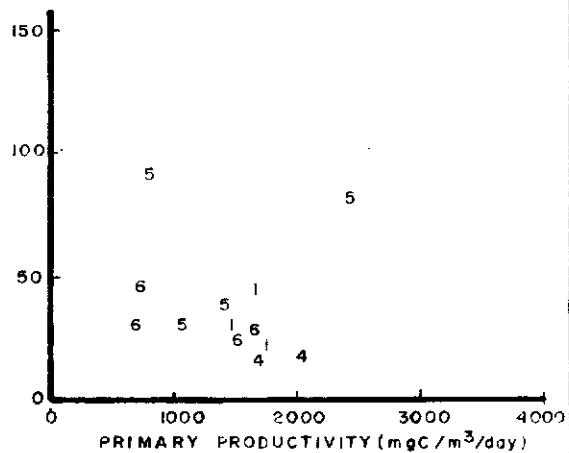

ALL 1973 DATA

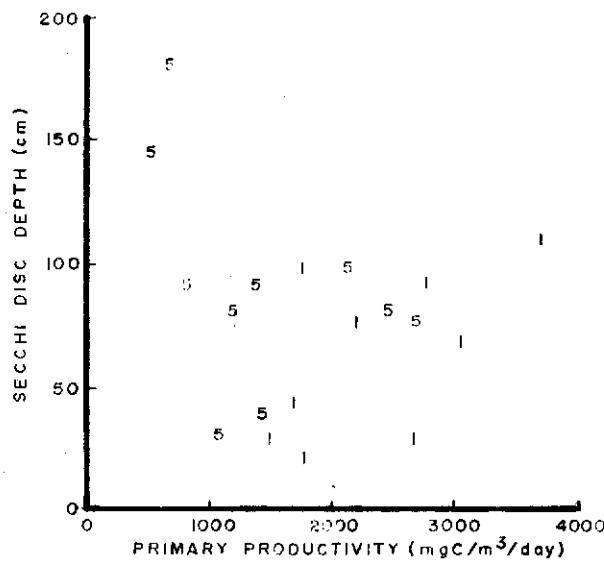

LAKE OKEECHOBEE 1973
SECCHI DISC DEPTH vs EFFECTIVE DISPLACEMENT INDEX

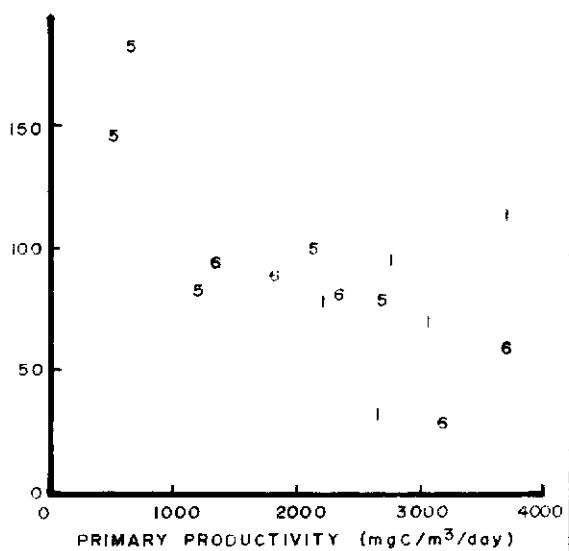

LAKE STATIONS
WITH SOFT BOTTOMS

WINTER (JAN-MAY) DATA

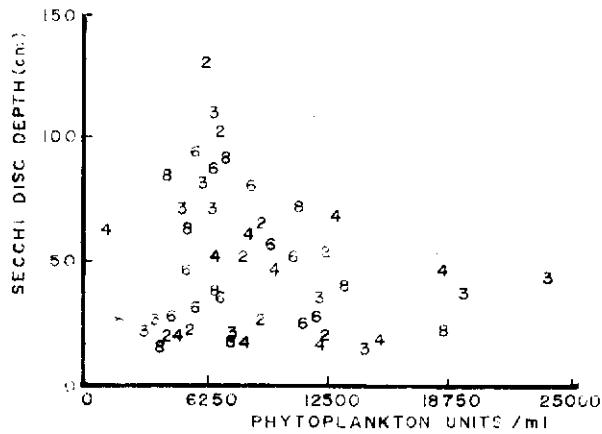

LAKE STATIONS
WITH HARD BOTTOMS

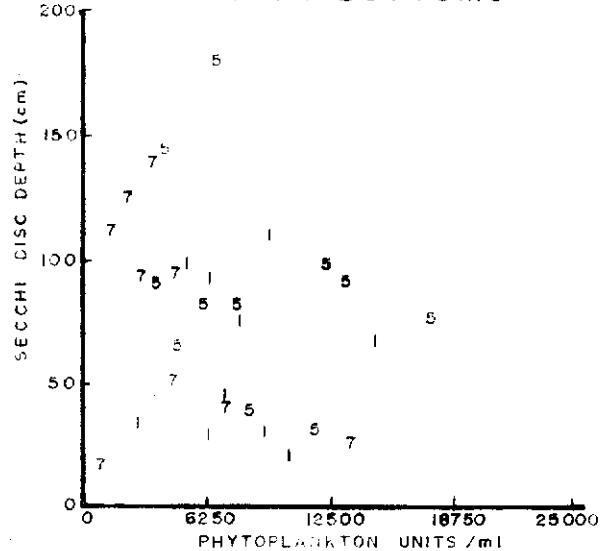

SUMMER (JUNE-OCT) DATA

ALL 1973 DATA

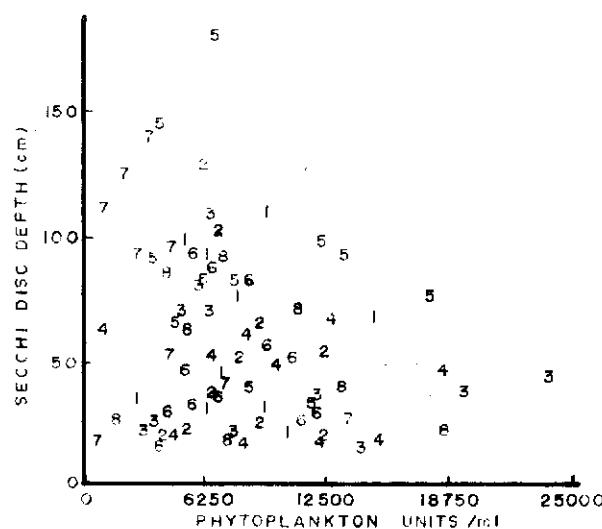

LAKE OKEECHOBEE 1973
SECCHI DISC DEPTH vs PRIMARY PRODUCTIVITY

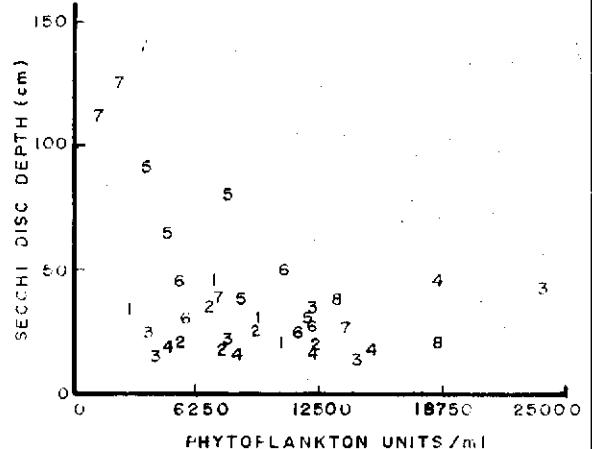

LAKE STATIONS WITH SOFT BOTTOMS

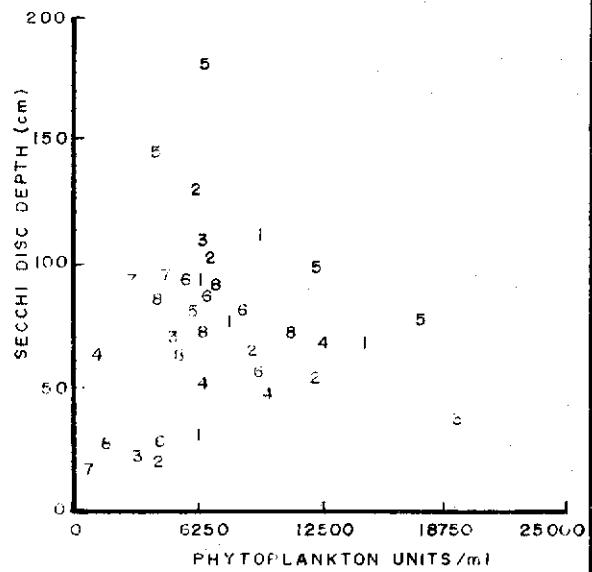

LAKE STATIONS WITH HARD BOTTOMS

ALL 1973 DATA

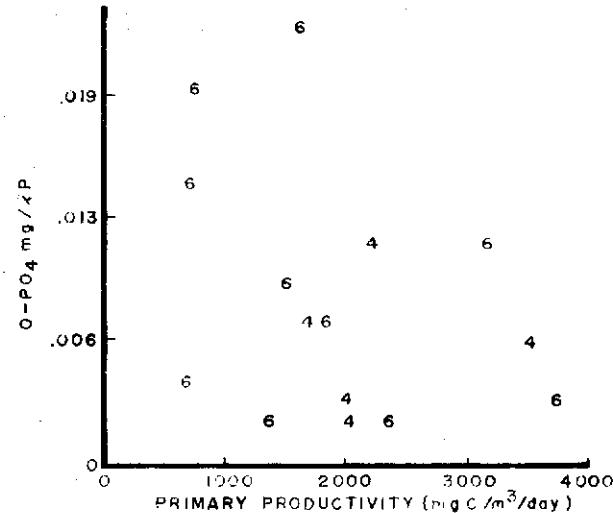

WINTER (JAN -- MAY) DATA

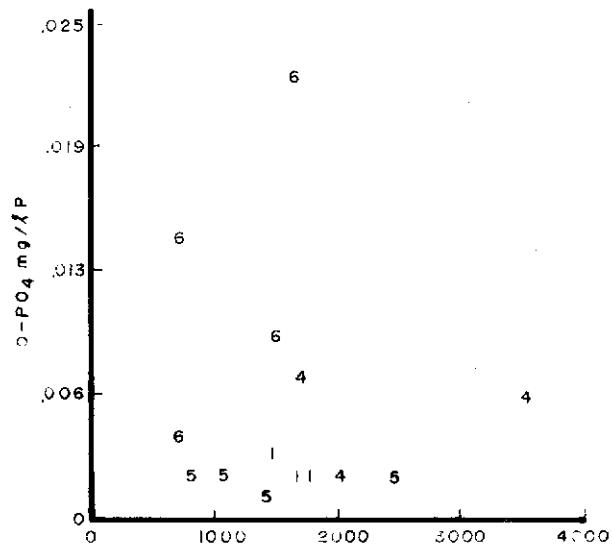

SUMMER (JUNE-OCT) DATA

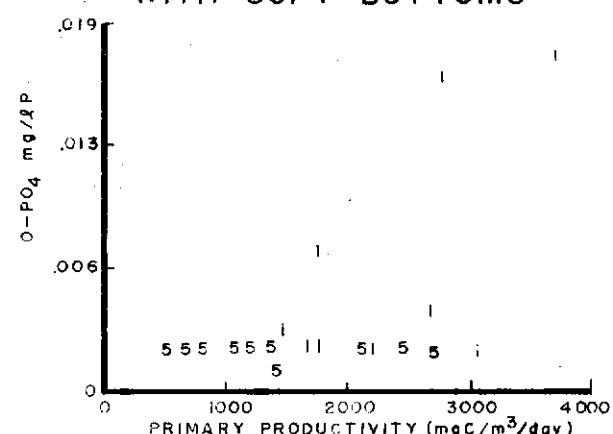

LAKE OKEECHOBEE 1973
SECCHI DISC DEPTH vs PHYTOPLANKTON COUNTS

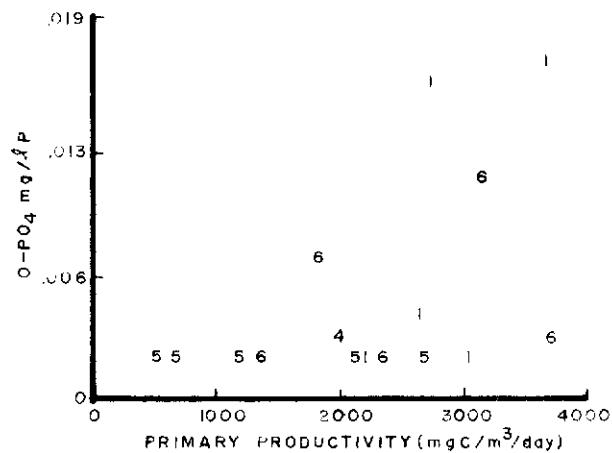

LAKE STATIONS
WITH SOFT BOTTOMS

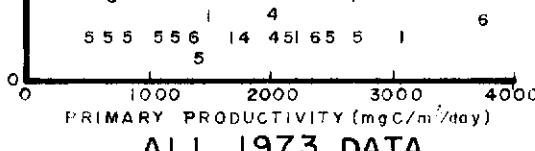

WINTER (JAN-MAY) DATA

LAKE STATIONS
WITH HARD BOTTOMS

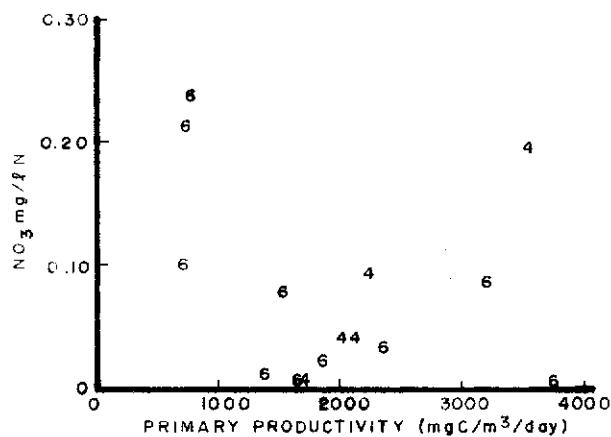

SUMMER (JUNE-OCT) DATA

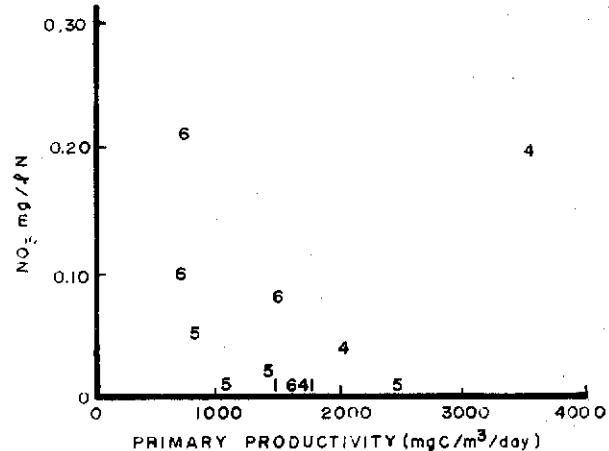

ALL 1973 DATA

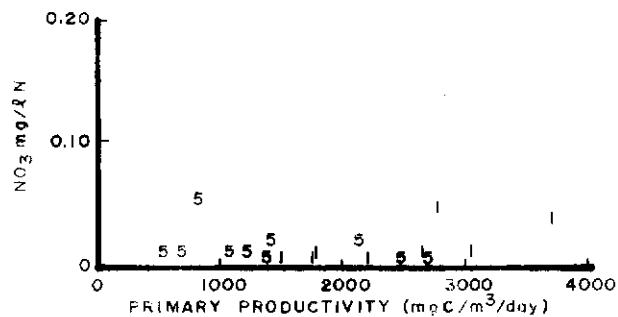

LAKE OKEECHOBEE 1973
ORTHO-PHOSPHATE vs PRIMARY PRODUCTIVITY

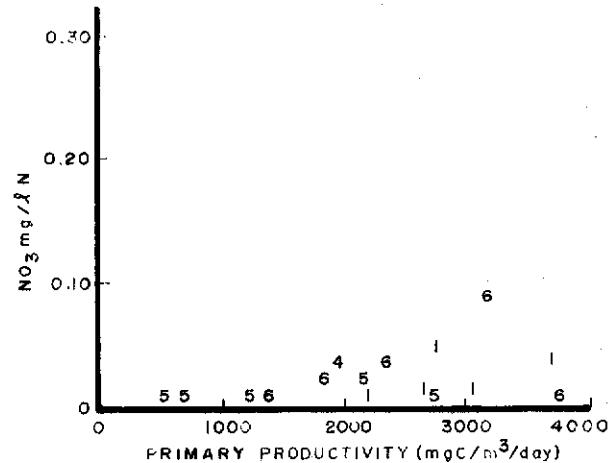

LAKE STATIONS WITH SOFT BOTTOMS

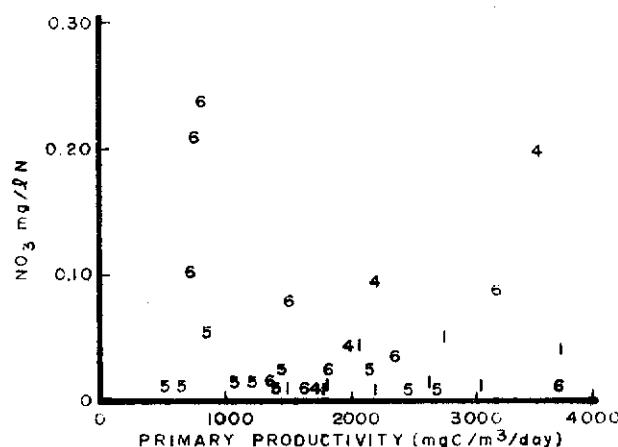

WINTER (JAN-MAY) DATA

LAKE STATIONS WITH HARD BOTTOMS

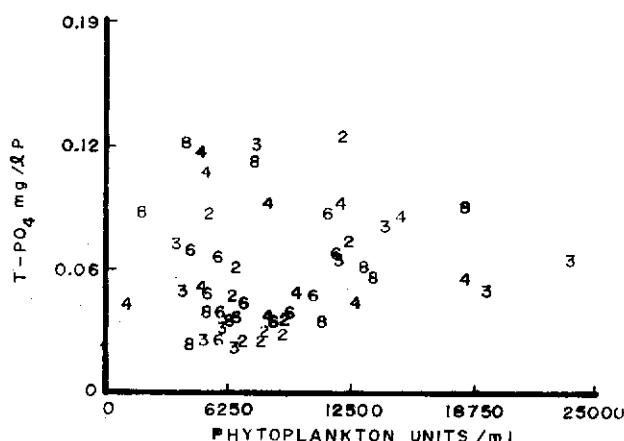

SUMMER (JUNE-OCT) DATA

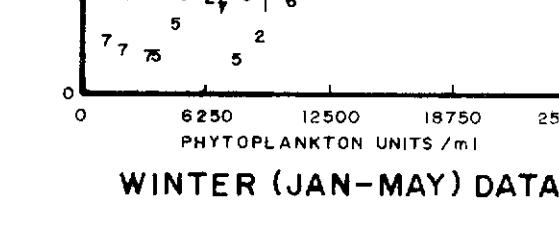

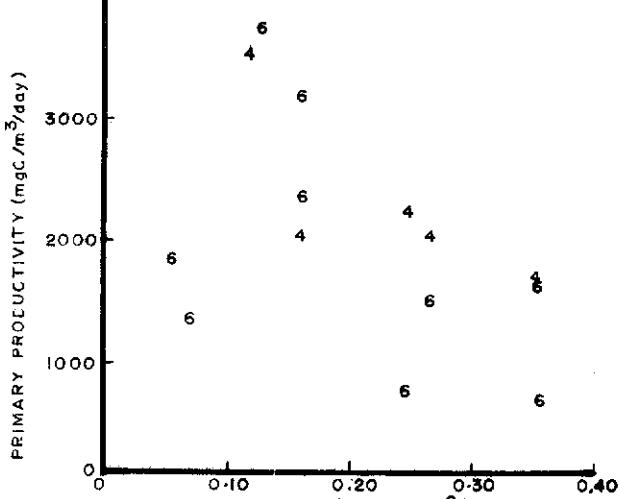

ALL 1973 DATA

LAKE OKEECHOBEE 1973
NITRATE vs PRIMARY PRODUCTIVITY

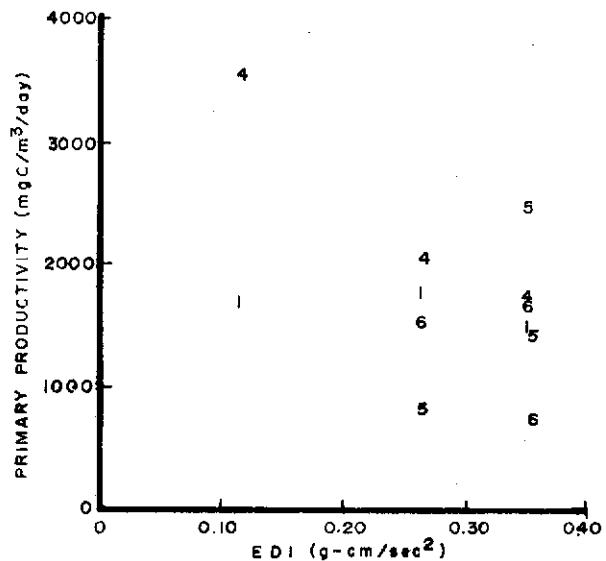

LAKE STATIONS WITH SOFT BOTTOMS

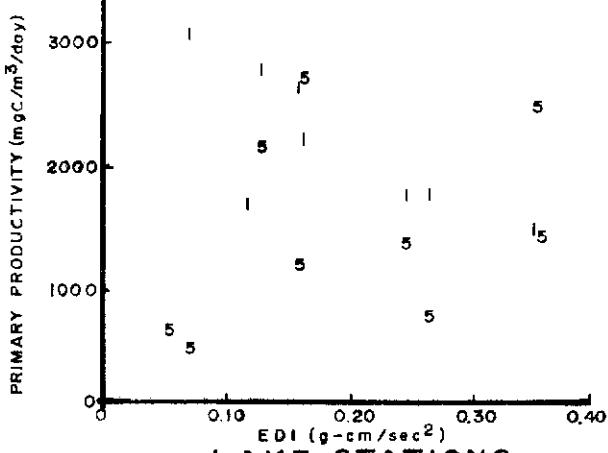

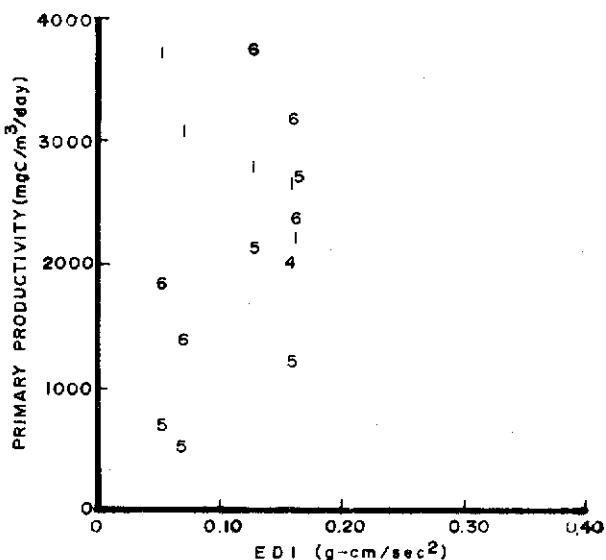

LAKE STATIONS
WITH SOFT BOTTOMS

WINTER (JAN-MAY) DATA

LAKE STATIONS
WITH HARD BOTTOMS

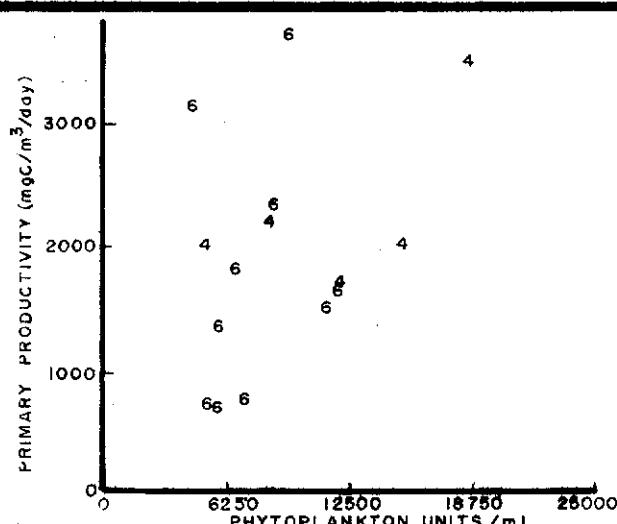

SUMMER (JUNE-OCT) DATA

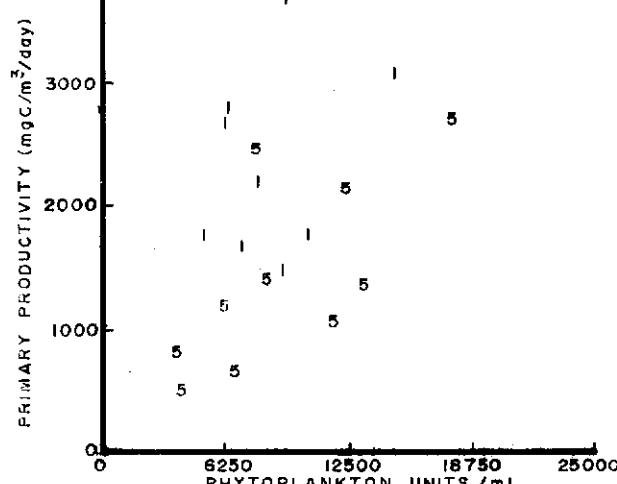

ALL 1973 DATA

LAKE OKEECHOBEE 1973

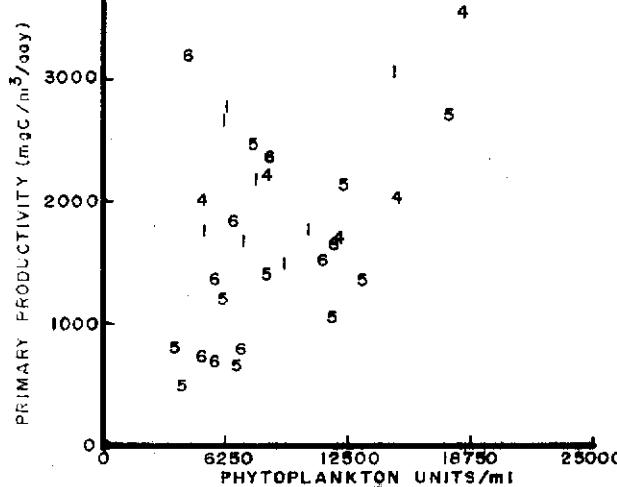

PRIMARY PRODUCTIVITY vs EFFECTIVE DISPLACEMENT INDEX

PHYTOPLANKTON UNITS / M²
LAKE STATIONS
WITH SOFT BOTTOMS

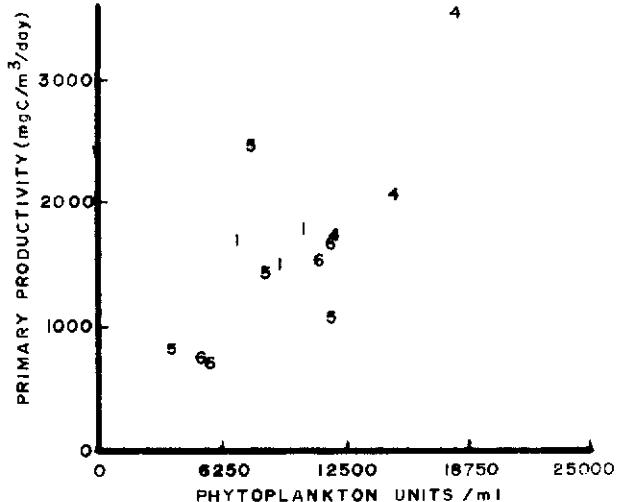

PHOTOPLANKTON UNITS M.M.
**LAKE STATIONS
WITH HARD BOTTOMS**

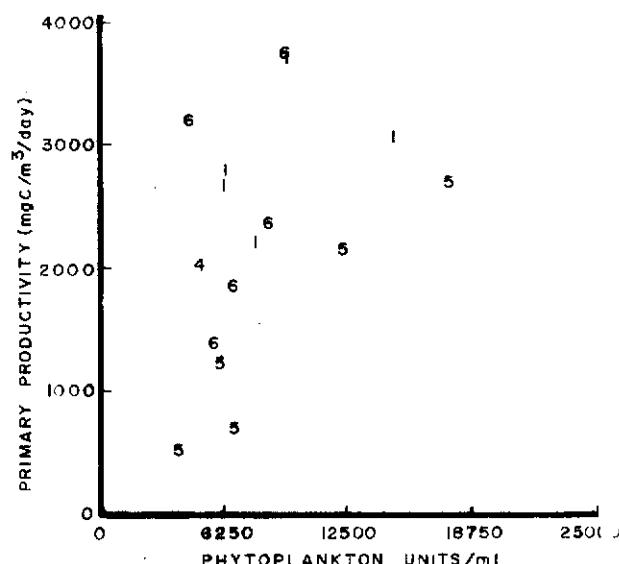

ALL 1973 DATA

LAKE OKEECHOBEE 1973
PRIMARY PRODUCTIVITY vs PHYTOPLANKTON COUNTS

WINTER (JAN-MAY) DATA

SUMMER (JUNE-OCT) DATA
